Ashley in 1937 reported the successful use of infant foreskins as homografts in 2 cases. The authors' investigations in a series of 24 foreskins from newborn infants as homografts on 5 different patients showed that none of them survived beyond the fourteenth day. They have therefore been unable to confirm the report of the successful use of infant foreskin as permanent homografts.

LOUIS T. BYARS, M.D.

Urgent Surgery in the Aged. CONROBT W. CUTLER, J.
A. M. Surg. 1947, 26, 765.

In this excellent article on surgical emergencies in the aged the author summarizes his experiences in 185 cases. The 304 patients who comprised the basis of these observations ranged in age from 60 to 102 years, an average age of 74 for the group.

The factors of deterioration and diseases of senility in chronic and advanced forms give the problem of urgent surgery in the older age group its special character. These conditions often entail difficulties in early and accurate diagnoses since the defects might mask or mimic conditions requiring quick surgical intervention. When an emergency arises, there is little opportunity to improve the patient's status and none to rectify the existing fundamental organic defects. Frequently encountered were myocardial degeneration, valvular heart disease, overweight, malnutrition, the results of previous coronary infarction or cerebral vascular accident, tuberculosis, lues, diabetes, anemia, vitamin deficiency states, hypoproteïnemia, arterial sclerosis, varieties of renal or hepatic dysfunction, or a combination of these defects. While the mortality attending surgery in this group was 44 per cent, the survivors represent surgical salvage or individuals who, unaided, would almost surely have succumbed. Of the 304 patients representing surgical emergencies, 15 were either in extremis or refused surgery, and all 15 succumbed.

These patients were poor operative risks and required maximum preoperative supportive and preparatory treatment. Such measures could not always be pursued to the desired extent without unduly delaying surgery. However, certain general principles

of therapy were adopted to meet the requirements of this type of case.

1. Every quickly available measure for support and protection should be utilized. Depleted blood and electrolytes should be replaced, impending acids should be prevented with glucose and insulin, new blood or plasma should be furnished, hydrolysis should be used to raise the blood protein level, concentrated vitamin solutions should be employed to promote tissue repair or to minimize hemorrhage, and anticoagulants should be used to overcome thrombotic or embolic states. When available, penicillin was administered every 3 hours preoperatively and postoperatively in doses of 100,000 units. The inability of the failing heart and kidneys to tolerate large quantities of fluid given rapidly by vein was recognized. The replacement of weight loss, and the administration of a high caloric diet and of morient proteins preoperatively were appreciated, but time was lacking to do this in these urgent cases.

2. The remedial operation should be undertaken with the least possible delay. Supportive measures should not delay unduly the performance of urgent surgery. Old persons deteriorate rapidly under stress, death of tissue, or obstruction of the intestinal tract. Delays in laboratory or x-ray investigation in ineffective efforts at intestinal intubation, or in trying to reach an unattainable optimum in the patient's condition may lead to failure.

3. With a minimum of trauma and in the shortest feasible time, the simplest procedure that will relieve the emergency should be done. Elective resections and anastomoses, meticulous repair of lesions, prolonged exploration of the bile ducts, cholecystectomy and plastic amputations will surely increase the mortality. The conditions for which operations were performed in this series over a 7 year period consisted of gangrene of the extremities, intestinal obstruction, inflammation and obstruction of the biliary system, appendicitis, and various infections.

4. Every means to safeguard the patient against postoperative complications should be employed and diligent watch should be kept for signs of their development. During the early postoperative hours shock was of first importance. Shock was combated with adequate amounts of blood and oxygen. Stimulant drugs were, in the main, disappointing. Preoperative and postoperative sedation must be cautiously managed since large doses of morphine are not well tolerated. Old people are particularly susceptible to pneumonia, wound disruption and sepsis. Many of them succumb even weeks after operation, to cerebrovascular accidents, coronary occlusion, uremia, anuria, and cardiovascular collapse. Pneumonia was the major cause of death (34% of deaths). Forty-nine per cent of the pulmonary complications began 10 days or more after operation. To prevent atelectasis, thorough aeration of the patient was regularly performed at termination of the operation and during the succeeding 24 hours; rebreathing procedures were carried out. Nurses were instructed to move and turn the patients fre-

quently to assure that a free airway was maintained and that no aspiration of vomitus occurred. These measures, plus the continued administration of penicillin were the best assurance also against pneumonia. The termination of bed rest was emphasized at the earliest possible moment, and it is believed that this practice reduced the incidence of phlebotomous and decubitus. In the patients who were out of bed early no case of wound dehiscence was encountered but it occurred in those who of necessity remained bedridden and was the product of distention, sepsis wound infection vitamin deficiency lowered blood protein or the presence of carcinoma rather than the muscular action produced by early rising. Phlebothrombosis though rare was treated by ligation and division of the superficial femoral vein of the leg showing involvement. If cryptogenic embolization occurred heparin plus dicumarol were relied upon.

General anesthesia properly chosen and administered was well tolerated by such patients. Ether was found to be reliable, safe and effective. Cyclopropane proved ideal combining low toxicity, rapid induction and recovery, and good relaxation permitting high oxygenation. Intocostin served to increase relaxation which permitted the use of smaller quantities of cyclopropane or ether. In view of the circulatory depression that frequently attends the use of spinal anesthesia, this method was treated with suspicion. Local anesthesia was found wanting for abdominal operations. Refrigeration anesthesia became almost routine after 1941. Pneumonia following operation, occurred in about the same relative frequency with each type of anesthesia employed and in about half of the cases it appeared to days or more after the anesthetic was given.

The pre-existing ailments of the patients were the greatest factor in a mortality of 44 per cent. Complications not directly attributable to the operation or to the emergency for which it was performed accounted for about half of the deaths. Prompt intervention may save well over half of the victims of acute surgical emergencies in old and chronically ill people.

Transplantation of the Hypophysis of Cadavers in Cases of Simmonds Disease (Transplantation de l'hypophyse de cadavre dans le cas de maladie de Simmonds) E. KURAWA. *Lyon chir.*, 1947 45 305

The author reports 4 cases in which very favorable results were obtained in patients with Simmonds disease by transplantation of the hypophysis from cadavers. Previous attempts at such transplantation have utilized as recipient sites the subcutaneous tissue, the abdominal musculature, the preperitoneal space, and the omentum. The author has utilized the region of the sympathetic nerves about the internal carotid artery. It is important to utilize a cadaver of the same sex and approximate age as the patient. All

of the wounds have healed by first intention and the patients have been ambulatory by the third day.

All of the 4 patients were greatly benefited and this is illustrated by striking photographic comparisons. Two of the patients died subsequently of tuberculosis. The other 2 are living and in perfect health.

EDWARD W. GIBBS, M.D.

Primary Hyperparathyroidism ROBERT W. SCHENKEL, E. R. KROSA, JR. and E. PERRY McCULLOUGH. *Cleveland Clin Q* 1947 14 246

The authors present 10 proved cases of hyperparathyroidism associated with parathyroid adenomas. On histological examination 6 adenomas were described as being composed principally of chief cells. Attention is directed to a functioning oxyphil cell adenoma which apparently is rare and the unusual occurrence of the same type of tumor in a blood relative.

In presenting observations on 10 cases of primary hyperparathyroidism the multivariety of clinical pictures, laboratory data and x ray findings are emphasized. The reports of the 10 clinical cases are given in detail. Hyperparathyroidism in its most typical form presents hypercalcemia, hypercalcaemia, hyperphosphatemia, and hypophosphatemia. With extensive skeletal involvement high levels of the variable types of symptoms and degrees of severity of the disease it is important to recognize the milder forms of the disease since they may prove fatal.

The symptoms and findings are divided arbitrarily into three main groups.

Group 1 includes those resulting from hypercalcemia. These consist principally of muscular weakness and decreased muscular excitability. The muscles are frequently flaccid and opposite in type from those of tetany. Constipation is common, and nausea and vomiting may occur. Polydipsia and polyuria occur frequently and may be sufficiently severe to simulate diabetes insipidus. One half of the patients noted polydipsia and polyuria. Pyralism was noted in one patient.

Group 2 includes the symptoms referable primarily to the urinary tract. These are generally the first manifestations of the disease. In 8 of 10 patients there was a history of renal colic and in 6 there was roentgenological evidence of renal calculi. In 4 there was a history of bilateral renal colic and in 3 roentgen findings of bilateral stones.

Group 3 includes the symptoms referable to the skeletal system. Ill-defined skeletal pain was present in 4 patients and epulides in 2 both of the latter patients had loose teeth. Pathological fracture was incurred in one kyphosis was present in another and giant-cell tumor was found in still another. A roentgen diagnosis of osteitis fibrosa cystica was made in 5 of the 10 patients. Resorption of the lamina dura was observed in 4 patients of this series. In 4 of the 10 patients the tumors were aberrant in location. One was found in the mediastinum at

the level of the second rib 2 were located in the substance of the thyroid and apparently took origin from the left superior gland and one tumor arose from the left inferior gland between the esophagus and the trachea. Of the 6 remaining adenomas, 1 arose from the right inferior and 5 from the left inferior parathyroid. Two were palpable prior to operation. Of the 10 removed only 1 was located on the right side. The electrolytic balance was restored in all of the patients by removal of the parathyroid adenoma. Partial disability remained in some resulting from renal calculi or parenchymal renal damage.

In the differential diagnosis of such problems, myelomatosis, hypervitaminosis D, simple bone cysts, and primary renal disease must be considered. The Sulkowitch test offers an instant method of detecting gross hypercalcemia. A presumptive diagnosis depends upon the detection of the characteristic alterations of the serum phosphorus and calcium.

The pathological physiology of primary hyperparathyroidism resulting from excessive parathyroid hormone is discussed. JOHN H. MORAROT, M.D.

Effects of Steroids on Lactation. J. C. BARRAMIENTE and G. ROSS M. C. MASON. *Endocrinology* 94:74, 1959.

Most of the theories presented to explain the absence of lactation during the second half of pregnancy at a time when the mammary gland is fully developed attribute a predominant but indirect role to the steroid secretions of the ovaries and placenta. Many attempts have been made to reproduce experimentally with ovarian hormones and other steroids the conditions prevailing during pregnancy in order to inhibit lactation.

Estrogens, probably mediated through the ovaries, inhibit lactation in normal animals and in accordance with the dose and the time of initiation of treatment this inhibition is partial or complete. Clinical investigations on the effect of estrogens upon lactating women have given contradictory results; however, recent well controlled studies tend to show that a diminished secretion can be obtained even during active nursing.

Progesterone and ethinyl testosterone are inactive in human beings. The androgens have given equivocal results both experimentally and clinically as have hormones of the adrenal cortex. Combined treatment with progesterone and estrogens inhibits lactation in ovariectomized rats, which indicates a possible synergism between the two hormones.

In a previous article the authors reported that among the various steroids administered in the form of pellets to both normal and spayed lactating rats, only estradiol and testosterone inhibited lactation in normal rats. Since the absorption from pellets varies with the nature of the steroids, the possibility remained that the inactivity of some compounds was due to this factor. Therefore in the current experiments the steroids were administered at the same dose level in the form of an oil solution.

Comparison of the present results with those reported previously shows that compounds which are inactive when administered under the form of pellets, inhibited lactation when given subcutaneously in oil solution. Since all the factors were identical otherwise, it can be assumed that the difference in the results was due to the factor of dosage.

In normal rats estradiol in daily doses of 1 mgm or less and testosterone, androstenediol, and dehydroisandrosterone in daily doses of 10 mgm much inhibited lactation. The inhibitory effect of androstenedione, methyl androstenediol, methyl androstenediol, ethyl testosterone, ethinyl testosterone, ethinyl androstenediol, and methyl testosterone was less marked. Progesterone, acetovyl progesterone, pregnenolone and desoxycorticosterone were inactive.

The lactation inhibitory effect of these steroids is mediated through the ovaries, since these steroids are inactive in spayed lactating animals. There appears to be some relationship between the inhibitory effect of steroids and their ability to inhibit lactation. DAVID H. LIPP, M.D.

The Adrenal Cholesterol and Ascorbic Acid Contents after Injury. STEPHAN LUDWIG and K. H. CHAMUTIN. *Endocrinology* 94:74, 1959.

The experiments reported herein were performed to determine the changes in adrenal cholesterol and ascorbic acid after a variety of stresses over a period of several days. The authors note that decreases in the cholesterol and ascorbic acid content of the adrenal glands have been reported to occur after injections of adrenotropic hormone, hemorrhage, scalding, exposure to cold, and trauma. It was found that injury may produce initial decreases but also causes delayed increases in the cholesterol and ascorbic acid content of the adrenal glands.

The following agents (symbols) and dosages were used:

Bis (B-chlorethyl) sulfide	(H) 0.4 mgm/kgm.
Ethyl bis (B-chlorethyl) amine HCL	(HN1) 0.4 mgm/kgm.
Methyl bis (B-chlorethyl) amine HCL	(HN2) 0.6 mgm/kgm.
Tris (B-chlorethyl) amine HCL	(HN3) 0.6 mgm/kgm.

Sodium pentobarbital anesthesia in control rats causes a significant hypertrophy of the adrenal glands within a few hours. The adrenal cholesterol content is significantly decreased by the anesthetic during the first 6 hours; the free cholesterol is not affected. The adrenal ascorbic acid content is decreased within a few hours after anesthesia, and increases to above normal within 24 hours.

Severe thermal injury causes a marked decrease in adrenal ester cholesterol content during the first 24 hours which is followed by a persistent and marked increase after this time. The ascorbic acid content follows a similar pattern. Mild to moderate burns cause significant increases in the cholesterol and ascorbic acid content. The free cholesterol content is

not affected. After the intravenous injection of tria (B chlorethyl) amide the adrenal ester cholesterol decreases significantly. Intravenous injections of 3 nitrogen mustard and sulfur mustard cause significant increases in the adrenal ascorbic acid content after 24 hours. Cutaneous application of sulfur mustard is responsible for marked adrenal hypertrophy. The ester cholesterol is increased after the third day.

In the present investigation hypertrophy of the adrenal glands was apparent as early as the third hour after anesthesia. Anesthesia plus saline injections, severe burns and intravenous injections of HN_3 . The adrenal weights returned to normal only in the anesthetized rats, and the data illustrate the rapidity of the response of the adrenal glands to minimal injury. The most marked adrenal hypertrophy in the series of experiments was noted in the rats treated cutaneously with sulfur mustard. The skin lesions in these animals were not particularly severe, but diarrhea was noted in about half of the animals treated. In the scalded animals the extent of hypertrophy was related to the time of exposure to the hot water.

The delayed increases in the adrenal cholesterol and ascorbic acid content appear to be manifestations of the adaptation syndrome following injury.

EXPERIMENTAL SURGERY

Toxoid Immunization in Experimental Gas Gangrene. W. A. ALTEMEYER, W. L. FURST, W. R. CULBERTSON, C. L. WADSWORTH and Others. *Ann Surg.*, 1947, 126: 509.

Thus far effective prophylaxis of gas gangrene has been limited to early and adequate surgery, but penicillin, administered parenterally, has been shown to be a very valuable therapeutic adjunct to surgery. Its prophylactic effect was greatest when it was used early and in massive doses and consisted of a limitation of the rate of spread and extensiveness of the infectious process as well as a marked retardation in the rate of death.

The possibility of producing active and effective immunity for this infection has been studied in recent years. Toxoids have been developed that have produced sufficient serum titers in laboratory animals to protect them from lethal doses of gas gangrene organisms injected into healthy muscle through fine needles.

From a surgical viewpoint however this does not simulate the conditions in clinical gas gangrene in which the organisms are found in large areas of grossly contaminated and devitalized tissue produced directly by trauma or indirectly by laceration or thrombosis of nutrient arteries. Furthermore, there is increasing evidence that the toxemia of gas gangrene is complex, being caused not only by the known bacterial exotoxins absorbed from the site of injury but also by other factors, possibly arising from the septic degeneration of devitalized tissue.

Consequently it seemed probable that the immunity reported thus far in experimental animals injected with toxoid inadvertently has been made to appear greater than it was.

The production of toxoid immunization against a more severe form of gas gangrene which closely simulates the clinical type was undertaken by the authors.

Guinea pigs were chosen as the experimental animals and *Clostridium welchii* toxoid was used to immunize them. Incisions under septic conditions were made in the thighs of the animals immunized and the muscles were crushed with Kocher clamps and then avulsed by twisting the clamps. In each wound 0.5 c.c. of an autoclaved and finely divided mixture of soil and cinders was placed. The edges of the wound were then closed. Finally 0.5 c.c. of the 1/100,000 minimum lethal dose was injected through the skin into the operative area containing the crushed muscle and dirt. Adequate controls were maintained.

These methods produced a more severe form of gas gangrene that required higher serum antitoxin levels (from 10 to 20 units per cubic centimeter) for protection than have been previously reported. The fact that it is more severe suggests that there is another toxic factor produced by the growth of virulent bacteria in crushed muscle.

Survival rates varied between 46 and 100 per cent under varying conditions. The best methods of producing long term immunity have not been established as yet but further work along this line is being done.

The high degree of immunity produced against the severe form of infection indicates that effective immunity is possible by the injection of toxoid against gas gangrene produced by the *Clostridium welchii* but the duration of the immunity is thus far undetermined.

Other studies are in progress to increase and extend the degree of immunity afforded by injections of *Clostridium welchii* toxoid and to produce similar immunization with toxoids of other clostridia associated with gas gangrene, in anticipation of the development of an effective mixed toxoid for human prophylaxis against clinical gas gangrene.

EDMUND R. DOMOGHUS, M.D.

Comparative Efficiency of Single and Multiple Dosage Regimens of the Penicillins. CHARLES G. ZORABO. *Bull. Johns Hopkins Hosp.* 1947, 81: 400.

Current practice in the use of penicillin G for the treatment of infections in man demands that a relatively constant blood concentration be maintained through frequent doses of penicillin. The author considers the experimental basis of different modes of administration in order to appraise how essential is the need for a constant penicillin blood level in the treatment of bacterial infections. Experiments were then undertaken to investigate the comparative efficiency of various dosage regimens of penicillin in a virulent hemolytic streptococcus in

fection in mice, and the pure penicillins G and K were used as the corative agents. The total amount of penicillin administered to the mice was kept constant and only the division of the total dose varied. No penicillin in oil and beeswax was employed and only the crystalline salts of penicillin G and penicillin K in aqueous solution were used.

In these experiments with a fulminating streptococcus infection in mice the controlling factor in the survival rate was the total dosage of the penicillins. Penicillin G and penicillin K had approximately the same effectiveness as antibacterial agents in mice when given every 8 to 24 hours as when given every hour. On this basis it seemed clear that the anti-streptococcal effect of aqueous penicillin G outlasted the measurable blood levels by many hours and the survival of the mice depended upon the total dosage administered over a fairly broad range of dose schedules. Large initial doses of penicillin G were advantageous in so far as they protected the mice for a much longer period than multiple smaller doses. The in vivo activity of pure penicillin K in streptococcal infections in mice was from one thirteenth to one-twentieth of that of pure penicillin G.

The author suggests that in the application of these experimental data to the treatment of bacterial infections in man one might try to use 300,000 units of penicillin G intramuscularly every 12 hours in the treatment of penicillin susceptible infections. In patients in whom treatment is begun late it would be important to try the effect of "large" initial doses of possibly 1,000,000 units immediately and again in from 8 to 12 hours followed by smaller doses administered at 4-hour intervals.

EDMUND A. CORVETT, M.D.

Comparison of the Carcinogenic Activity in Extracts of Human Liver and Other Human and Animal Organs. PAUL E. STENZEL, D. WERNER STAMMER, and MIRIAM N. BOYARD. *Cancer Res.* 1947 7 273.

The authors cite the possible existence of carcinogenic carcinogens in man. A considerable number of investigators have demonstrated tumor-inducing activity in extracts of noncancerous human liver. Both carcinomas and sarcomas have been induced by liver extracts: the former by application of the latter by injection of the extract. The tumor-inducing factor was found in the total lipid extract with benzene, and in the nonsaponifiable lipid fraction extracted with ethylene dichloride or with petroleum ether.

The authors attempted to discover endogenous carcinogens in other human organs as well as the liver by injecting extracts subcutaneously into mice of the C 57 black strain. Extracts of human liver, spleens, colons, hearts and livers were used; these were obtained both from cancerous and noncancerous individuals. Livers from stillborn infants and swine livers and bovine livers were also tested.

The experiments demonstrated a tumor-inducing factor in the nonsaponifiable lipid fraction of human liver from cancer-bearing and noncancerous persons. The combined percentage yields of sarcoma in two of two strains was 22.7 and 48.4 respectively. The extract from livers of stillborn infants was also carcinogenic. Hog liver showed evidence of activity but beef liver was negative. In the study of organs and tissues other than the liver only the cancerous spleen showed evidence of considerable tumorigenic activity.

AORTIC VALVULOTOMY

Experimental Methods and Early Results

HORACE G SMITHY M D F A C S H RAWLING PRATT THOMAS M D and
HENRY P DEYERLE, M D Charleston, South Carolina

IN a preliminary report (7) a technique was described for division of the aortic valve in dogs with a view toward developing a method which might be applicable to the surgical treatment of aortic stenosis in human subjects. The present report concerns the early results obtained by the technique described a presentation of a second method of valvulotomy and a comparison of the results obtained by the two procedures.

The first method consisted in brief of passing a specially devised valvulotome (7) through the wall of the ascending aorta manipulating it proximally within the aorta until the instrument became engaged within one of the cusps of the aortic valve (Fig 1). By manipulation of the sliding harbed blade of the instrument, the valvular leaflet was divided perforated, lacerated or partially avulsed (Fig 2a to g). Control of hemorrhage from the aorta after the withdrawal of the valvulotome was accomplished by tamponade of the aortic opening with an absorbable gelatin sponge or with oxidized cellulose secured in place by stay sutures in the periaortic fat. The results obtained by this method are considered below.

The second method of aortic valvulotomy which has proved safer simpler and more ef-

fective than the first consisted of division of one or more valvular leaflets by approaching the valve through the wall of the left ventricle using the same valvulotome described in the transaortic technique (7). The procedure was carried out in large adult mongrel dogs as follows. The thoracic cavity was opened through an incision in the left seventh intercostal space intravenous sodium pentobarbital anesthesia being used. Intrapulmonic positive pressure was obtained during the operation by an artificial respirator which delivered an interrupted flow of atmospheric air through an endotracheal catheter. Full exposure was obtained by self retaining rib-spreading retractors. The pericardium was opened widely from its aortic reflection to the cardiac apex. A traction suture of silk was placed in the left ventricular wall so as to deliver the inferior portion of the heart into the wound. In this manner the cardiac apex was exposed clearly and a purse-string suture of catgut was placed in an avascular area of the wall of the left ventricle at or near the apex. A small incision was made through that portion of ventricular wall included in the purse-string suture. The sheath of the valvulotome was manipulated through the incision into the cavity of the left ventricle with the hooked blade drawn up within the protecting sheath so as to avoid damage to the intraventricular structures. At this point, the purse-string was drawn taut about the valvulotome by an assistant and was held snugly

From the Departments of Surgery and Pathology Medical College of the State of South Carolina.

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, New York, September 8- 947

about the instrument during manipulation. By this means, the procedure was carried out without bleeding. The instrument was advanced in the ventricle toward the aortic valve with one hand, while the index finger of the opposite hand was manipulated beneath the ascending aorta at its most proximal portion so as to lie flush with the aortic ring. Using the latter finger as a guide, it was found that the distal end of the valvulotome could be interposed almost exactly between the three aortic valvular leaflets. When its position was determined with relative certainty the barbed blade was projected forward so as to lie astride the free margin of a valvular leaflet and the instrument then was withdrawn proximally into the ventricular chamber thus dividing the aortic cusp (Fig 3). After division of the cusp which was denoted in most instances by the immediate appearance of a thrill detected by the palpating finger at the aortic ring, the valvulotome was withdrawn from the ventricle with the blade pulled back into the sheath. Upon removal of the instrument the ends of the purse-string suture were tied by the assistant thus closing securely the ventricular incision without hemorrhage. The thorax was closed after inflation of the lung.

RESULTS OF THE TRANSAORTIC METHOD

The observations recorded herein pertain to a total of 37 animals subjected to operation by a transaortic approach. The data concern operative mortality and gross and microscopic findings as regards the valvular lesions and the aortic wounds through which the valvulotome was passed. Animals were sacrificed at intervals varying from 24 hours to 18 days after operation.

Mortality. Of 22 animals previously reported (7) attempts at closure of the aortic wound after withdrawal of the valvulotome were made in 7 animals by direct suture of the defect. The results were unsatisfactory inasmuch as severe hemorrhage occurred accounting for the operative death of 5 of the 7 animals so treated. In the remaining 15 the aortic wound was closed by tamponade with a gelatin sponge held in place by stay sutures in the periaortic fat with only 3 operative deaths. The mortality for the group was 36 per cent.

TABLE I.—ANALYSIS OF OPERATIVE DEATHS.
TRANSAORTIC METHOD

	Number of animals	Deaths	Mortality per cent
Aortic suture technique	7	5	71
Gelatin sponge technique	5	5	100
Oxidized cellulose technique	2*	0*	0*
Periaortic fat suture alone	5	3	60
Totals	17	13	76

*Operative survival; death from secondary postoperative hemorrhage.

The same technique was applied to a second group of 15 animals; there were 2 operative deaths due to uncontrollable hemorrhage from the aorta, a mortality of 13 per cent. In the surviving animals a gelatin sponge was used at operation in 8, oxidized cellulose in 2, while in 3 a purse-string suture in the periaortic fat was tied snugly over the aortic opening without the use of an underlying hemostatic agent to tamponade the aortic wound.

Recapitulation of these figures reveals that the total operative mortality in 37 animals subjected to transaortic valvulotomy was 76 per cent (Table I). This excessive figure is due obviously to the loss of 5 animals subjected to direct closure of the aortic wound. Of the remaining animals treated by methods other than aortic suture, there were 5 operative deaths in 30 subjects, a mortality of 17 per cent.

In addition to the operative deaths, 3 animals died of secondary hemorrhage from the aortic wound on the third postoperative day. In each instance oxidized cellulose was the hemostatic agent used to tamponade the aortic opening. It is significant that secondary hemorrhage did not occur in any instance in which a gelatin sponge or periaortic fat sutures alone were used.

Gross findings. At the time the animals were sacrificed, gross examination concerned the appearance of the aortic wound and the type of valvular lesion produced. Wide variation in the size and persistence of the aortic opening was noted. In the 27 animals surviving the operation, the aortic opening was found to be either healed completely or of very small size in 7, persistent and of large extent (greater than the original size) in 12 of

TABLE II—VALVULAR LESIONS PRODUCED BY TRANSAORTIC METHOD IN SURVIVING ANIMALS

Type of lesion (Fig.)	Number of animals	Incidence per cent
Perforation	3	30
Laceration	6	
Avulsion	4	5
Division	6	
Absence of lesions	3	
Totals	27	100

approximately the original dimensions in 8. The time elapsing between operation and autopsy seemed to have little effect, complete closure of the wound being found in some after 72 hours on the one hand, persistence of a large defect after 16 days on the other. Of striking significance is the fact that there was no instance of extensive extravasation of blood into the periaortic tissues and no evidence of aneurysm in those animals treated by the gelatin sponge technique or by periaortic fat suture alone, this being the case despite persistence of the opening on the intimal surface. In the 2 cases in which absorbable cellulose was used massive secondary hemorrhage occurred, resulting in death of the animals through a "blowout" in the periaortic fat on the third postoperative day. In each there was found at autopsy a widely patent communication between the aorta and the pleural cavity.

Although persistence of the aortic opening on the intimal surface was present in 20 animals sacrificed from 3 to 18 days after operation, thrombus formation was noted in only 1 case. This animal was sacrificed on the fifth postoperative day. A large rent in the intimal surface of the aorta was present but was effectively sealed off from the periaortic structures by the overlying gelatin sponge and its anchoring periaortic fat. Protruding from the intimal defect was an elongated thrombus, the unattached end of which was hanging free in the aortic lumen; the clot measured 2.5 centimeters in length and 0.5 centimeter in width. Evidence of embolic phenomena was not found. A second animal sacrificed on the seventh postoperative day was found to have an unusually large rent in the intimal surface of the aorta through which a segment of the

Fig. 1. Transaortic method of valvulotomy.

overlying gelatin sponge protruded into the aortic lumen. Despite the presence of a foreign body anchored within the vascular stream, a thrombus was not found at autopsy and no evidence of embolic phenomena was detected.

The valvular lesions produced by the transaortic approach are denoted in Figure 2, showing a considerable variation in the type of defect occurring in the affected leaflets. Similarly, the resulting auscultatory murmurs assumed either a systolic or diastolic character according to the extent of valvular division. Of the 27 animals surviving operation, the aortic valve showed no evidence of a lesion in 3, which was due probably to failure of the valvulotome to become engaged in a cusp passing instead into the chamber of the ventricle during systole. This represents an operative failure of 11 per cent (Table II). In the remaining 4 animals, the lesions consisted of valvular perforation, laceration, partial avulsion or division (Table II). A perforative defect was noted in 30 per cent (Fig. 2 a and b), some variety of laceration in 22 per cent (Fig. 2 c and d), partial avulsion in 15 per cent (Fig. 2 e) while extensive division of a leaflet was accomplished in 6 animals or 22 per cent (Figure 2 f and g). Postoperatively auscultatory murmurs were demonstrable in each in

Fig. 2. Various types of lesions produced by trans-aortic valvulotomy: a, a d 1, perforation, occurred in 30 per cent; c and d, laceration, occurred in 22 per cent; e, partial avulsion occurred in 5 per cent; f and g, extensive division occurred in 15 per cent.

stance in which a lesion was produced. A soft blowing diastolic murmur typical of aortic regurgitation occurred in those animals in which division or partial avulsion of a cusp had been accomplished. In the group showing perforation or short laceration of the leaflets, a harsh systolic murmur was demonstrable.

Microscopic findings—aorta The size of the healing aortic wounds through which the valvulotome was passed varied considerably

The manner of healing was essentially the same in all defects which closed successfully and consisted of fibrous tissue proliferation between the divided edges of the aortic wound. The proliferating fibroblastic elements were derived almost exclusively from the adventitial coat and there was little participation by elements of the media and none by the intima except for the lining endothelium. There was no attempt at regeneration by the musculo-

Fig. 3. Transventricular method of valvulotomy a, and lesion of extensive valvular division b produced in majority of animals.

elastic elements of the media but some of the intervening fibrous tissue contributed to closure of the defect. In relatively few instances the divided edges of the aortic wound remained in close approximation and the narrow defect was completely filled with actively growing fibroblasts (Fig. 4). In the majority of instances there was outpouching of the aortic wall at the site of the operative wound. The aneurysmal pouch involved the adventitia and periaortic fibroadipose tissue. Figures 5 and 6 illustrate extension of the endothelialized defect into the adventitial coat with failure of elastic tissue regeneration from the lateral margins. Complete endothelialization of the aneurysmal sac as noted in the latter illustrations occurred as early as 14 days. Figure 7 depicts in detail the endothelial regeneration within the aneurysmal sac. Outpouching into the substance of the wall of the aorta occurred in some cases regardless of tamponade of the aortic opening with a gelatin sponge or closure of the defect by suture of the overlying fat without a sponge.

Microscopic findings—*aortic valves* Division of a valve leaflet produced in the initial phase edema interstitial hemorrhage loss of endothelium along the divided margins and variable degrees of actual necrosis in the area of division.

There was in general during the first 3 to 5 days no leucocytic reaction. Fibrin deposits on the severed margins of the cusps

occurred within 3 days after division and persisted for as long as 14 days. The fibrin was invaded early by fibroblasts (Figs. 8 and 9) and was completely replaced by collagenous fibrous tissue as early as 14 days in some animals. Endothelialization occurred concomitantly with the fibrous organization. The edges of the incised leaflets did not show appreciable distortion but assumed a blunt rounded or club-like shape. None of the healing valves showed any evidence of infection.

RESULTS OF THE TRANSVENTRICULAR METHOD

Fifteen animals were subjected to aortic valvulotomy by a trans-ventricular approach. The results reported herein pertain to the operative mortality of the procedure and to both gross and microscopic changes occurring in the heart and the affected valves. Animals were sacrificed at intervals varying from 3 to 26 days after operation.

Mortality There was 1 operative death in 15 animals undergoing transventricular valvulotomy a mortality of 7 per cent (Table III). Death was due to acute dilatation of the left side of the heart occurring immediately after complete division of an aortic leaflet. A second animal died of empyema and acute purulent pericarditis on the seventh postoperative day. All other subjects recovered without infection and remained well until sacrificed.

Gross findings Certain changes occurring during operation were significant particularly

Fig. 4 Aortic wound at 80 days shows complete filling with vascularized fibrous tissue. (Hematoxylin and eosin stain, $\times 80$)

the varying degrees of cardiac dilatation detectable grossly which were noted immediately after division of an aortic leaflet. Since the valvular lesions produced by the transventricular approach were more extensive than those resulting from transaortic valvulotomy a greater degree of aortic regurgitation was effected. The sudden increase in the volume of blood within the left ventricle produced marked dilatation of the left side of the heart in some animals. As noted above acute dilatation was of such degree as to cause death in 1 animal while in 2 others it resulted in complete cessation of both left ventricular and left auricular contractions for approximately 40 seconds the heart gradually regaining its tone and resuming a normal rhythm as it adjusted itself to the increased ventricular output. In the remaining animals, grossly demonstrable dilatation occurred in 8 without cessation of ventricular activity while in 3 dilatation was slight or absent as determined by gross inspection.

Electrocardiographic tracings were made before operation immediately before and after valvulotomy after closure of the thorax

and shortly before the subjects were sacrificed. All tracings were taken while the animals were under sodium pentobarbital anesthesia. Lead II only was used throughout the experiments. In approximately two-thirds of the animals, rather marked disturbances of rhythm were noted during manipulation of the heart incident to placing the purse-string suture in the apex and during insertion of the valvulotome. The other one-third of the group showed surprisingly little interference with cardiac rhythm. In some subjects an inverted T wave was noted prior to operation, but a constant finding in all animals was inversion of the T wave after closure of the wound, due presumably to myocardial damage inflicted by entering the ventricle and by tying the purse string suture. Tracings made after the fourteenth postoperative day showed return of the T wave to a normal curve. Figure 10

concluded was noted uniformly in each instance.

The valvular defects produced by the ventricular approach were similar in type, either complete or partial division of a leaflet being accomplished in each of the 14 surviving animals (Table IV). Figure 3a denotes the lesion of complete division which occurred in 64 per cent of the animals; the remaining 36 per cent showed incomplete division of a leaflet but in each instance of sufficient degree to

produce definite aortic regurgitation. The resulting auscultatory murmurs were diastolic in character in most instances typical of those heard in clinical aortic regurgitation. Gross defects of the borders of the divided leaflets were smooth and showed no tendency toward healing. The formation of vegetative thrombi on the defects did not occur in any instance.

At the point through which the valvulotomy was passed into the ventricular chamber there was found to be considerable induration

of the myocardium about the purse string suture of catgut as late as 20 days after operation. However the endocardium appeared smooth and thrombus formation was found in only one instance. The latter occurred in an animal dying on the seventh postoperative day of acute empyema and suppurative pericarditis and consisted of a small fibrinous plaque attached firmly to the endocardial surface of the ventricular wound.

Microscopic findings—myocardium of left ventricle. The myocardium through which the valvulotome was passed showed varying evidence of necrosis inflammatory reaction and healing. The changes were essentially those of a healing infarct. In some animals tissue reaction was minimal after 25 days and consisted of fibrous scarring with little destruction of the myocardium. In others however iso-

lated areas of myocardial necrosis were noted as late as 25 days, with retardation of the normal healing process. In these instances, the islands of necrotic muscle were demarcated by peripheral fibrosis which was believed to produce local ischemia. There were no instances of endocardial thrombus formation with the exception of one animal having empyema and

pericarditis noted above and no evidence of cardiac aneurysm at the site of the ventricular wound.

*Microscopic findings—*aortic valves The histologic changes in the aortic leaflets were the same as those which occurred when the transaortic approach was used. Endothelialization of the margins of the divided cusps was found to be complete as early as 14 days (Fig. 13).

The lack of marked deformity, absence of vegetations and the fibrous repair and endothelialization of divided cusps are shown in Figure 13.

COMMENT

The need for a safe technical approach to the surgical treatment of chronic valvular disease of the heart has been recognized for many years. Recent developments in cardiac surgery, notably the splendid contributions of Blalock in pulmonic stenosis, have created a stimulus for reinvestigation of the problem. The idea is not new. The surgical treatment of mitral stenosis was suggested by Brunton in 1902. Following animal experimentation it was attempted clinically by Cutler and his associates (4) in 1924. In 1929 Cutler and Beck (3) summarized their personal experiences in the surgical treatment of 8 cases of mitral stenosis and added 4 collected cases of chronic valvular disease subjected to operation. The mortality for the entire group was

83 per cent. Since these patients were treated much progress has been made in thoracic surgery and particularly in the administration of positive pressure inhalation anesthesia. These advances, combined with recent developments in chemotherapy and a sound present-day concept of the prevention and treatment of shock, minimize many of the former hazards and should permit recognition of Cutler's methods with significant reduction in mortality.

In comparing the two experimental techniques reported herein with a view toward their application to human subjects, certain considerations are immediately obvious. First it seems clear that transaortic valvulotomy is an impractical method. The possibility of clinical application is rendered unlikely because of the high mortality incident to technical difficulties in controlling hemorrhage, the uncertainty of producing an adequate valvular lesion (Table II) and microscopic evidence of the probability of later aneurysm formation. On the other hand, transventricular valvulotomy was performed with technical simplicity with an operative mortality of only 7 per cent and with the production of uniformly satisfactory valvular lesions. On the basis of these factors alone the superiority of the ventricular approach is self-evident. Furthermore, the latter method is applicable theoretically to clinical mitral stenosis as well as to aortic stenosis.

A second consideration in the possible application of transventricular valvulotomy to clinical aortic and mitral stenosis concerns the type of operative correction contemplated. It would seem that simple incision of a heavily scarred (and often calcified) aortic or mitral valve would afford an inadequate means of increasing the size of the narrowed orifice. It is likely also that an incised wound in the fibrous valvular ring would heal eventually. With these considerations in mind, actual removal of a segment of the thickened valvular ring (partial valvulectomy) would appear preferable to simple incision or division of the stenotic valvular orifice (valvulotomy). The valvulotome used in the experiments herein described would be therefore unsuitable in human subjects. The development of a suit-

able instrument designed to remove a segment of a fibrotic or calcified ring between strong biting surfaces is now in progress. Such an instrument should be of the smallest diameter compatible with an effective biting mechanism in order that the extent of damage sustained by the ventricular wall may be minimized as much as possible.

A third factor of importance is the disturbance in cardiac rhythm which was demonstrable in some animals (Figs 11 c and 12, c d) during manipulation of the valvulotome. Clinically it is obviously inadvisable to induce ventricular fibrillation and tachycardia during operation in a patient having myocardial damage. The preoperative systemic administration of quinidine sulfate or the topical application during operation of procaine, as reported by Mautz, should minimize or possibly eliminate some of the more serious arrhythmias.

The final consideration of significance concerns the advisability of converting a stenosis into a regurgitation. Regarding the mitral valve it is generally agreed that stenosis is a much more serious lesion than regurgitation causing marked restriction of the patient's activities and affording a poor prognosis. This may not be the case however in lesions of the aortic valve. There is a group of patients not withstanding, in the young adult range of years having aortic stenosis of sufficiently advanced degree to interfere substantially with their activities. The difficulties of these individuals are largely mechanical in origin and consist of inadequate left ventricular output which produces chronic hypoxia becoming

acute during exertion, persistently low systolic blood pressure and decreased coronary blood flow all of which are the result of a small, contracted aortic valvular orifice. Improvement in each of these factors could be logically anticipated by increasing the size of the valvular orifice to permit a greater ventricular output. In our present state of experimentation however one can only speculate upon the relative effects either beneficial or harmful of aortic regurgitation and aortic stenosis, inasmuch as a satisfactory method of producing experimental aortic stenosis is lacking. The work of Shaw and his associates is a valuable contribution in the study of experimental valvular lesions other than those of the aortic valve.

SUMMARY

The technique of aortic valvulotomy in dogs by a transaortic and transventricular approach is described and a comparison of the results of the two procedures is presented. Certain considerations in the possible application of the experimental methods to clinical valvular disease of the heart are discussed.

STUDIES ON VAGOTOMY IN THE TREATMENT OF PEPTIC ULCER

II Clinical Evaluation

KARL A. MEYER, M.D. F.A.C.S., PETER A. ROSI, M.D. F.A.C.S. and
I. F. STEIN, JR., M.S. M.D. Chicago, Illinois

THE history of vagotomy and its early use in man as a treatment for peptic ulcer has been reviewed previously (32-34). Clinical experience with partial vagotomy and experimental evidence show that incomplete vagotomy is of little if any value in the treatment of peptic ulcer. Most of the early workers in this field used surgical procedures which resulted in only partial vagus section. Dragstedt, who has suggested complete vagotomy as a treatment for peptic ulcer, has reported favorable results (7-11, 38) and has created a widespread interest and controversy in the subject.

In June of 1946 a study of vagotomy in the treatment of peptic ulcer was started at the Cook County Hospital on the surgical service of the senior author. During the following year vagus section was performed on 35 patients with peptic ulcer.

SELECTION OF CASES

Patients demonstrating very severe ulcer diathesis were selected for this study. In all 35 cases previous medical or surgical management had failed to give relief from pain. The indications for surgery were based on prolonged periods of ulcer symptoms with one or more complications (Table I).

The duration of symptoms ranged from 1 to 36 years with an average of 11 years. There were 16 instances of previous perforation, 19 patients had had previous bleeding, 10 of whom had had massive hemorrhage, and 6 patients had pyloric obstruction which in 3 patients, was complete. Repeated attacks of severe epigastric pain were present in 31 of the 35 patients and in 12 the pain was intractable.

From the Hektoen Institute for Medical Research of the Cook County Hospital and from the Departments of Surgery of the Cook County Hospital and Northwestern University Medical School, Chicago.

Dr. Stein is Abbott Fellow in Surgery, Northwestern University Medical School.

Duodenal ulcer was present in 26 patients, marginal ulcer in 3 patients following gastroenterostomy, marginal ulcer in 4 patients following gastric resection, and 1 patient had a gastrojejunal colic fistula following gastric resection (Table II). One patient had a pyloric ulcer shown to be benign by biopsy at the time of closure of a perforation 2 months before vagus section. This was the only gastric ulcer in the series.

SURGICAL APPROACH

The transthoracic approach as described by Dragstedt (10) was employed in the first cases. A 2 to 3 centimeter portion of the nerve was resected at approximately 6 centimeters above the diaphragm. No attempt was made, however, to remove the distal branches of the vagi extending to or below the diaphragm as described by Dragstedt and Moore (35).

The transabdominal approach as described by Dragstedt (7) has been employed in the remaining 26 cases and is preferred since:

1. Exploration of the gastrointestinal tract allows examination of the viscera for confirmation of diagnosis and for other intra-abdominal pathology.

2. The site of the ulcer may be examined, and if marked scarring is present, a simultaneous gastroenterostomy is performed to prevent gastric retention.

3. Patients have a quicker convalescence and less postoperative discomfort.

4. The percentage of patients having incomplete vagotomy will not differ greatly whether the transthoracic or transabdominal method is used, provided that a careful search is made for all vagus fibers in the region of the diaphragm.

From an anatomical point of view, complete vagotomy can be done most satisfactorily at the diaphragm at which location the smaller branches of the vagi tend to form into large

TABLE I —INDICATIONS FOR VAGOTOMY

trunks (3, 5, 24). Due to marked anatomical variation in the distribution of the nerves complete vagus section may be difficult to achieve in about 8 per cent of cases (3).

POSTOPERATIVE CARE

Early in this study postoperative intra gastric suction was maintained for 2 to 3 days. Following a case of acute gastric dilatation and retention the gastric decompression was continued for 5 days in order to prevent the marked gastric dilatation which often followed vagus section. The patients were kept in fluid electrolyte and nitrogen balance by parenteral administration of saline, dextrose, protein digests and blood. The patients were usually out of bed the day after surgery and ambulatory by the second day. Small frequent feedings of clear liquids were given on the sixth and seventh postoperative days and small frequent feedings of general liquids on the 2 following days. A soft diet was usually given on the tenth postoperative day and a general diet was allowed after 2 to 3 weeks. The patients were permitted to eat anything they chose but were cautioned against overeating for the first few months because of the danger of producing an

Fig. 1. Barium meal demonstrating cardiospasm, gastric dilatation and retention 2 weeks following vagotomy.

acute dilatation in the vagotomized stomach. There were no further cases of acute gastric retention and dilatation.

RESULTS

In general, clinical results have been excellent. Following surgery all patients had immediate relief of ulcer pain. For the first time in many years 31 of the 35 patients are leading an unrestricted life. Ulcer management including dietary and medical treatment has been eliminated completely. Following vagotomy the majority of the patients noted a change in the bowel habit. They had one or two soft bowel movements a day whereas preoperatively almost every patient gave a history of constipation. Troublesome diarrhea occurred in 2 patients. However the diarrhea disappeared spontaneously after 2 months. Thirty patients had satisfactory weight gain. Thirty-one patients expressed themselves as being

TABLE II —TYPE OF SURGERY IN 35

Fig. 2 The effect of insulin on gastric acidity before and after vagotomy

well satisfied with the results. The most striking results from the standpoint of relief of intractable ulcer pain have occurred in 8 patients with marginal ulcer.

One patient died on the eighth postoperative day due to uremia and lower nephron nephrosis which followed a blood transfusion reaction. Recurrence of ulcer symptoms with positive x-ray evidence of peptic ulcer occurred in 4 cases. One patient developed an acute gastric retention and dilatation on the tenth postoperative day which was treated effectively by gastric lavage followed by the administration of doryl (carbamylcholine 36). The initial

dose of doryl was 0.25 milligram subcutaneously followed by 2.0 to 4.0 milligrams orally 3 times a day before meals. This patient developed a persistent foul belching which lasted 5 months in spite of treatment with doryl or urecholine (10 mgm. 3 times a day before meals). These foul eructations have ceased and the patient is entirely asymptomatic.

The symptoms of cardiospasm verified roentgenologically in 2 instances (Fig. 1) were noted in 3 patients about 3 weeks postoperatively. The dysphagia, substernal discomfort, and regurgitation of food were spontaneously relieved in from 1 to 3 weeks.

One patient has a loss of appetite with a failure to gain weight and 1 patient has occasional vomiting. One patient who had an

Fig. 3. Average basal secretion before and after vagotomy 6 hours previous fasting)

Without gastroenterostomy	343		3	
b. Incomplete vagotomy	687	16	19	1

Fig. 4. The effect of histamine on gastric acidity before and after vagotomy (average of 11 patients)

excellent clinical result, was readmitted to the hospital 3 months following vagotomy with a bronchopneumonia from which he died. Autopsy showed the pneumonia to be unrelated to the previous vagotomy.

The most frequent and disturbing complication was gastric retention and distention but this has been controlled by the use of a gastroenterostomy if pyloric obstruction was present by careful postoperative management and by occasional use of doryl or urecholine (36).

Thirty patients were tested for completeness of vagotomy by the insulin test (34). Fourteen to 16 units of regular insulin were injected intravenously after a 1 hour control period of basal secretion and motility. The effect of insulin hypoglycemia on gastric secretion and

motility was noted for $1\frac{1}{2}$ to 2 hours. The average preoperative and postoperative results in 22 patients with duodenal ulcer are shown in Figure 2. Preoperatively there was a marked rise of the free acid level following insulin hypoglycemia and spontaneous or insulin induced hunger contractions were present in the fundus of the stomach. A similar response postoperatively is positive evidence of incomplete vagotomy whereas the absence of an acid response to insulin hypoglycemia and of hunger contractions either spontaneous or insulin induced, is indicative of complete vagotomy. Of 30 patients tested 5 had incomplete vagus section in that the result was doubtful, and 1 had recurrence of vagal function after 9 months a total of 8 patients having

Fig. 5. The effect of caffeine on gastric acidity before and after vagotomy (average of 12 patients)

doubtful or incomplete vagotomy. Four of these have had recurrence of ulcer symptoms.

Roentgenologic studies were made preoperatively 2 weeks postoperatively and again at 2 to 9 months after surgery (33). Two weeks after complete vagotomy there was a marked delay in the initial gastric emptying. After 4 hours there was 50 to 70 per cent retention of barium in the stomach and in only a few cases had the barium reached the cecum. No strong peristaltic waves were seen in the stomach. Gastric retention was present in patients without gastroenterostomy and in those with a large gastroenterostomy but was less in the latter group. Marked contractions of the stomach and prompt gastric emptying were noted 5 to 10 minutes following the administration of 0.25 milligram of doryl subcutaneously (36). Delay in gastric emptying was less marked after 3 months however it was still present 9 months following complete vagotomy.

Physiologic studies show marked changes in gastric function following complete vagotomy (35). The night secretion is markedly reduced (Table III). The basal secretion after 16 hours of fasting is practically eliminated (Fig. 3). The secretory response to histamine is reduced from 12.7 to 3.6 milliequivalents per hour or 72 per cent (Fig. 4). The secretory response to caffeine is reduced from 7.2 to 0.96 milliequivalents per hour or 86 per cent (Fig. 5). Spontaneous type I, II and III hunger contractions after 16 to 24 hours of fasting are not present in the fundus of the stomach up to 9 months after complete vagus section.

DISCUSSION

The early complications of vagotomy such as cardiospasm, gastric dilatation or retention are easily controlled and do not detract from the value of vagotomy in the treatment of peptic ulcer. There are two important questions, however, which must be answered before vagotomy can be accepted unreservedly.

1. What percentage of patients will have recurrence over a period of years?
2. Are the changes in gastric function permanent following complete vagotomy? If so will there be late sequelae due to either changes in gastric function or to changes in other organs innervated by the vagi?

Theoretically recurrence may be explained by either failure to resect all the vagus fibers, regeneration of the vagi or by factors unrelated to vagus nerve section. Since section of all the vagus nerve fibers going to the stomach is necessary in order to obtain a good result in the treatment of peptic ulcer a determination of completeness of vagotomy should be conducted on all patients. This can best be ascertained by use of the insulin test (34). Most of the clinical reports on vagotomy do not specify the number of patients having had incomplete vagus section. One clinic reports that 48 per cent of patients had incomplete vagus section (17). In our series, 5 of 35 patients, or 14 per cent, had incomplete vagotomy postoperatively as shown by the insulin test. In 1 case which tested complete following surgery there was a mild recurrence of ulcer distress after 9 months. An insulin test at this time showed incomplete vagotomy. This may have been due to regeneration of the vagus nerve fibers. Thus, at the end of a year 6 patients, or 17 per cent, were known to have incomplete vagus section. Four of these have had recurrence of ulcer distress. One had a very severe recurrence of epigastric distress, hematemesis, and vomiting 6 months after incomplete trans-thoracic vagotomy for a marginal ulcer. The patient was reoperated upon and a transabdominal vagotomy performed which subsequently tested complete. The patient has had an excellent clinical result to date.

Gastroenterostomy has a very limited place in the treatment of peptic ulcer because of the high incidence of postoperative gastrojejunal ulcer. Incomplete vagotomy and gastroenterostomy may result in similar gastrojejunal ulceration.

The permanency of the altered gastric function following complete vagotomy is not yet certain. The early changes in gastric function provide evidence for a reappraisal of the present concept concerning the relationship of the vagus nerves to gastric function. Pavlov proved that the vagi are the sole mediators of the cephalic phase of gastric secretion. The vagi are the predominating but not the only factor contributing to the interdigestive period of gastric secretion as shown by the reduction but not complete abolition of the night and

basal secretion following complete vagotomy. Also the gastric response to secretagogues is partially dependent upon vagus function as shown by decreased gastric response to caffeine and histamine after complete vagotomy.

Illustrative of the change in the gastric secretory mechanism following complete vagotomy is a patient who prior to surgery, had spontaneous secretion of free acid up to 78 clinical units during the basal period and 135 clinical units following 10 milligram of histamine phosphate. After complete vagotomy there was no free acid during the periods of basal secretion or following histamine. An achlorhydria was present.

In view of these changes in gastric function following vagotomy one must consider the possibility that the other organs innervated by the vagus will also be affected. The influence of complete vagotomy on the pancreas, liver, gall bladder, intestines, adrenals and kidneys has not been reported. One possible instance of an exacerbation of hypertension following vagotomy is reported (26).

In spite of lack of information concerning recurrences and late sequelae, complete vagotomy is considered the treatment of choice for marginal ulcer following gastric resection.

SUMMARY AND CONCLUSIONS

Thirty five patients with peptic ulcer have had vagus section and have been followed clinically from 6 to 15 months. Complete vagotomy causes immediate cessation of peptic ulcer distress with apparent healing of the ulcer. There are marked changes in gastric secretory and motor mechanisms following complete vagotomy. It is not certain to what extent the altered gastric function is permanent. Little is known of the effect of vagotomy on the other organs innervated by the vagi.

It is still too early to make a final evaluation of vagotomy in the treatment of peptic ulcer. Until more information is available concerning the incidence of recurrence of ulcer distress and the possible late sequelae, the use of vagotomy should be limited to clinical investigation with one exception. Complete vagotomy is the method of choice in the treatment of marginal ulcer following gastric resection.

STEEL WIRE SUTURES LOCAL ANESTHESIA, AND IMMEDIATE AMBULATION IN THE TREATMENT OF HERNIA

GERALD H. PRATT M.D., F.A.C.S., New York, New York

THE advantage of metallic suture material in surgery had been known since Marion Sims successfully closed the first vesicovaginal fistula with silver wire. His success demonstrated that these sutures would be effective where no others would succeed. The use of wire generally was not feasible because of the difficulty in handling the silver wire, its lack of strength and the cost. The introduction of stainless steel wire by Babcock in 1932 and its great success in his hands as well as those of his followers has opened new fields of surgery for us and to our minds marks one of the great surgical advances in years comparable even to chemotherapy. Difficult fistulas and sinuses may be approached with confidence and operations on mucous membranes (i.e. cleft palate etc.) are no longer awesome.

The success of the stainless steel wire suture on the serosa of the bowel and in such areas as duodenal stump closures can be attested by those who have tried it. Not only do structures heal better but the infection incidence is greatly reduced. Jones' reduction in the incidence of infection from 27.5 to 0.85 per cent in large bowel surgery by changing from catgut to steel wire is sufficiently significant in this respect. Since 1935 this suture has replaced all others in abdominal wound closures in our practice. Some surgeons, however, are not aware of its wide adaptability to general surgery. It is the purpose of this paper to show its use in hernia repair where it is of particular value.

Hernia is a common surgical affliction. In the examination of 2,700,000 men 4 per cent of those between the ages of 21 and 30 years were rejected for military service because of hernia. Approximately 10 per cent of all males from the age of 20 to 70 years have a hernia on one side and of these 60 per cent have sufficient findings on the other side as to make them physically disabled. It follows that in

general surgical practice 1 of every 5 or 6 operations will be for this condition.

Surgical cure after operation is somewhat uncertain particularly in the older patients. Most surgeons when questioned will claim a very low recurrence rate but when large series of carefully followed patients are studied an incidence from 10 to 30 per cent is usual. Erdman reported 650 hernias with a recurrence rate of 7 per cent and this favorably compared with the 8 per cent in L. Davis' series of 754 at the Massachusetts General Hospital. If the patient is elderly however the chance of cure after operation is less. Of 659 hernias in patients over 50 years of age operated on at the Ruptured and Crippled Hospital in New York (Hospital for Special Surgery) failure resulted in 25.8 per cent of the operations. In the Grace and Johnson series failure resulted in 30 per cent in the indirect type and in 38 per cent in the direct type. This lack of success in from 10 to 30 per cent of operations for hernia repair carried out by competent surgeons has led to a search for factors other than technique as the cause of failure. Anatomical studies were made to determine if there was a type of physique which made repair impossible. Moorehead was able to observe over a period of years the progress of nearly 100 per cent of his New York subway patients and he reported reoperation in 10 per cent. The Army and Navy where a fair check can be maintained by the health record system also showed a large recurrence rate. At a large Naval hospital where I served on the surgical service 12 per cent of all hernia operations were for recurrence. The average recurrence of direct hernias reported in the literature was 24 per cent.

While technique and skill play a large part in success, a hernia repair can succeed only if the structures remain united until healing is complete. In this respect, suture material plays an important part. Surgeons, in reoperation for

Fig 1. Babcock type hernioplasty. Sac is dissected to internal ring, base is trans-fixed and transplanted behind the lateral edge of rectus muscle. The lateral edge of rectus is united to the shelf of the inguinal ligament medially; the cord is not elevated or disturbed. The external oblique is imbricated. All sutures are of interrupted steel wire.

some complication frequently have noted the complete disintegration of absorbable sutures within a few days time. This inconsistency in the action of catgut stimulated a search for other suture materials. The effort was hastened by the knowledge that certain patients have a catgut allergy, an antipathy which causes them actually to digest and destroy the material when it is in the body. Babcock was among the first to notice and report this manifestation after investigating it for considerable time in 1933. Cumette Kraissal and others proved this allergic factor while Hinton showed that 1 of every 10 patients who has been operated upon was sensitive to an 0.8 per cent solution of fresh sheep gut. When such allergy exists not only is there poor or no wound healing but there is a tendency to wound infections. Whipple was able to reduce this wound infection incidence to one-third merely by discarding catgut. Even when there is not catgut sensitivity, the absorption of the material at the time of greatest activity can be responsible for the weakness in the wound. This thought is further strengthened by the fact that most recurrences are just

above the pubic area, the point of greatest strain. It is fair to assume that the suture material must bear considerable responsibility for the high hernia recurrence rate.

During my 4 years' association with Dr Babcock we were much interested in the suture problem. Under his supervision many experiments with various sutures were made by me and continued by Preston Holland and Large. All types of catgut, silk, linen, cotton, plastic material, and wire were sutured through the skin and observations were made at 5, 7, and 14 days in order to study the effect of the material in human subjects. In reoperations pathological sections were made of both the sutures and the surrounding tissues. Control animal experiments for tissue reaction and suture were carried out. Later, I continued these experiments in New York. The results of this work are on record and need only to be mentioned. The following observations were made:

1. In 7 to 14 days there is a distinct tissue reaction to catgut whether of the plain or chromic type, the reaction varying from a flare to a true pustular formation.

Fig. 2. Modification of Babcock hernia technique with the formation of a new internal ring. The conjoint tendon is incised medially and sewed after the cord is displaced in that direction. The lateral edge of the rectus is united to the sheath of the inguinal ligament. All sutures are of interrupted steel wire.

2. In 50 per cent of silk sutures retained over 10 days some necrosis of tissue occurred around the suture.

3. Cotton sutures while having less reaction than silk are of inconsistent tensile strength sutures on the same spool varying at times as much as 5 pounds in the force they withstand.

4. Wire sutures if not tied too tightly (to constrict tissue) will have no reaction around them 90 per cent of the time.

5. Wire for its size has the greatest tensile strength and therefore can be used in proportionately smaller sizes.

After considerable study and further testing wire was adopted first by Dr. Babcock therefore at the Babcock clinic as early as 1933 and in my own practice since 1935 it has been used exclusively to close all abdominal wounds.

During the recent war while serving in the Pacific area with the Navy I carried several spools of Babcock wire constantly with me since many areas were not supplied with the suture. I am certain that some unexpected good results in infected wounds were brought about through the employment of the wire

suturing material. I refer particularly, to certain intestinal anastomoses and exteriorization operations in the presence of grossly infected wound conditions in which results were far better than would have been expected had other suture techniques been used.

In 1942 I presented a series of 85 consecutive cases of inguinal hernias which were repaired with steel wire at the N. Y. Post Graduate Hospital. During my service in the Navy it was possible to observe the results of repairs with many different suture materials, the type varying usually with the preference of the chief of surgery. When I returned to this country all hernia operations performed at the second largest Navy hospital in this country the one at St. Albans, were done with the steel wire technique. Approximately 60 hernia operations were done every month. A comparison of these operations with those done by other techniques has been made by Ferguson and Fraser. I wish to report only on those performed by me or under my personal direction before, during and since the war.

All of these operations were done under local infiltration and block anesthesia (1 per

Fig. 3. Modified Bassini repair. The cord is elevated, the sac is resected at the base, and the base is transplanted under the edge of the rectus. A new internal ring is established by dividing the conjoint tendon and moving the cord medially. All sutures are of interrupted steel wire. The external oblique may be sutured above or below the cord.

cent procaine) except the recurrent ones these being done under spinal anesthesia. Three hundred and seventy six hernia operations are thus included with the other I previously reported all performed with the same wire technique. Fifty-eight per cent of these were indirect, 21 per cent direct, 12 per cent recurrent and 9 per cent femoral or umbilical type. The first 143 and the last 70 of these operations were done with a modified Babcock technique. In the Babcock type of operation the cord is not elevated or disturbed. The sac is freed and resected at the internal ring and its base is transplanted behind the lateral edge of the rectus muscle No. 36 steel wire being used (Fig. 1). If the internal ring is very large we have modified this technique by incising the conjoint tendon medially and pushing the cord in that direction and sewing the conjoint tendon below the cord thus making a new internal ring and closing the old one completely (Fig. 2). The repair then follows with the lateral edge of the rectus being sutured with No. 32 or No. 34 wire to the iliopectineus or actually to the peritoneum of the pubis. The lateral edge of the rectus then is united to the shelf of the inguinal ligament the

conjoint tendon being folded into the inguinal canal up to the internal ring. Lateral to the internal ring the conjoint tendon is sutured to the shelf. The external oblique fascia is imbricated with No. 35 steel wire and the skin is closed with No. 36 steel wire.

In the remainder of the cases the repairs were of the Bassini type. The change to the Bassini operation was made while I was in the Navy in order to make the operations uniform and thus save confusion among the officers sent to us for surgical training.

The follow up in the first 86 and the last 70 cases (156) is entirely complete and covers periods of from 12 months to 12 years. The follow up in the remainder of the operations (220) performed in the Navy is incomplete but each patient was followed up for 6 months. There have been 4 known hernia recurrences: 1 in a large hernia twice recurrent before where a distressing postoperative cough caused surgical failure within a few days after operation and another in an enormous hernia with stretched out fascial planes repaired by a trainee. Subsequent repair has been successful so far. While all of these patients have not as yet been followed for a sufficiently long

period they have been observed well past the critical first 6 month period. Seventy five per cent of recurrences are demonstrable within 12 months.

Certain other factors are worthy of mention. Formerly in the Navy a routine flat in-bed period of 21 days was a routine procedure after such an operation. In the 6 months prior to the installation of wire suture material in this Navy hospital the bed days averaged from 9 to 13. With the introduction of the wire suture technique and with the use of local anesthesia the patient was encouraged to get up upon his return from the operating room and to go to the head the first day. Previously we had always been afraid to have hernia patients out of bed early. With the use of the wire technique the danger of early ambulation is over. In the group of patients with hernias repaired by the wire technique including the patients with recurrences the average number of days in bed was 3.4 days and 85 per cent of the patients were up the first day. This early ambulation reduces materially the bladder and chest and thrombosis complications. Men were returned to duty in 21 days, and in the Navy that meant full duty including hoisting and carrying their hammocks and seabags.

The lack of physical discomfort after these operations was outstanding. While it is usual to order morphine routinely after hernia operations, a record of this group showed that

there was only one hypodermic of morphine given per each patient in the first 72 hours.

The complications following these operations were comparable to those in any group in which in many instances, the operation was done by a surgeon under training. There were 9 wound hematomas, 12 wound infections, 9 serous pockets, 14 stitch abscesses, 1 atelectasis (after local anesthesia), 5 pneumonias (3 after local and 1 after spinal), 1 coronary occlusion and 1 partial wound separation. There were no genitourinary complications and no thrombosis. There were no deaths in the group.

SUMMARY

1. Recurrence after hernia operations remains high even in the hands of competent surgeons.

2. Of the nonabsorbable suture materials, steel wire to our minds best fulfills the fundamental suture criteria that it be of great tensile strength, cause minimal tissue reaction, and that it can be inserted with little trauma.

3. Over a period of 10 years it has been used exclusively and satisfactorily in hernia repair.

4. The steel wire repair of hernia combined with local anesthesia and early ambulation has resulted in less recurrences, fewer bed and hospital days, and less discomfort and disability to the patient than when repairs were made with other suture material.

above the level of the lesion. The exception of course is the mid or high cervical lesion which so commonly results in early death. It is hardly tenable furthermore that shock can be said to persist for weeks at a time with the patient in good condition save for his paralysis. This interval should be designated as one of *depressed reflex activity*. But all reflex activity is rarely gone. In fact the genital reflexes (active ischiocavernosus and bulbocavernosus muscle reflexes with erection) may appear immediately to be persistent over a long period of time. Erections occurring immediately have been noted in patients with transected or incompletely crushed cords, both in the cervical and thoracic regions and this reflex has been seen to remain active and easily provoked for as long as 4 years after injury. Indeed it is through stimulation of the external genitalia (but not with nocuous stimuli) the perineal skin and the inner surfaces of the thighs that one may first note the onset of the second stage or the state of *heightened reflex activity*. With the beginning of this second phase there appears the early visceral and vasomotor reflex changes and flexion-extension or adduction of parts of the lower extremities. After the first day or two there is frequently though not characteristically an almost normal appearing flexor movement of the toes on plantar stimulation. During this period there is retention of urine and catheter care is necessary. The bowels require enemas but ordinarily automaticity of the bowels if it develops at all will begin at an earlier date than similar function of the bladder. Knee and ankle jerks are absent during the early days after injury. Bladder irrigation and enemas seldom cause flushing, sweating, headache or crampiness in the abdomen before the 4th week has passed. The skin below the level of the lesion becomes quite dry, pale and lifeless especially on the feet and ankles and tissue turgor is poor. It is during these first few weeks when vasomotor stability is lost in the skin (4) that bed sores are most likely to develop.

Except for the ever-present specter of bed sores, the patient is usually a cursing problem of ordinary degree during the period of depressed reflex activity taking into account

the special attentions to the bladder the skin and the state of nutrition. Neurological recovery if it is to occur will show some signs fairly early and the persistence of depressed reflex activity with or without any plantar responses, usually means that a complete physiological if not anatomical lesion exists. Sherrington discussed the period of shock in a few paragraphs, hardly improved upon to this date when he stated, "Spinal shock appears to take effect in the aboral direction only. Section behind the brachial enlargement disturbs little if at all the reactions of the fore limb although the number of headward running channels of conduction ruptured by such a section is enormous. On the aboral side of the transection depression is profound. The view of Golts and his school that spinal shock is a long lasting inhibition due to irritation by trauma is not, I think, really tenable. Were the mere irritative actions of the trauma the cause it is not easy to see why the nervous centers near the trauma should not be depressed on either side of for instance a spinal transection headward as well as backward. The practical absence of spinal shock on repetition of the trauma further back is explicable by its then causing little further aggravation of the interruption of the nervous channels concerned with vascular tone and vascular reflexes those channels having already been ruptured by the previous transection somewhat further headward. There remains the further question as to whether spinal shock is a phenomenon of inhibition. The condition of the spinal reflex-arc in spinal shock appears to resemble a general fatigue rather than an inhibition. It renders difficult and uncertain the process of conduction along the reflex-arc as judged by the discharge from the terminal neurone. This suggests a loosening of nexus between the links of the neurone chain composing the arc a defect of transmission at the synapse. I think therefore, that spinal shock is either due to irritation by trauma or to the main a phenomenon of inhibition. The rupture of certain aborally conducting paths appears to induce it. The deeper depression of reaction into which the higher animal as contrasted with the lower

sinks when made 'spinal' appears to me significant of this that in the higher types, more than in the lower, the great cerebral senses actuate the motor organs and impel the motions of the individual

The early phase of reflex depression has been studied in four groups of cats in which injury of the spinal cord was produced. Eight cats were operated upon and severe pressure exerted upon the 4th thoracic segment of the cord for 3 6 12 18 24 48 72 and 96 hours following which the animals were killed. A second group was similarly operated upon except that at the end of these periods of pressure the animals were again operated upon and the mechanism of pressure removed. In a third group 2 cats were subjected to electrocoagulation of all the blood supply of the isolated 4th thoracic segment and in a fourth group 4 other animals were subjected to total maceration and complete destruction of the cord at that level. Certain of the animals in the second series regained some function but in the animals of all groups the so called shock was equally early and severe. As has already been pointed out, the genital reflexes and the occasional flexion of the toes on plantar stimulation, particularly with noxious stimuli occurred in patients as early and as actively regardless of whether or not the cord was completely transected or severely crushed or whether any other form of trauma was the cause of interruption of normal physiological function. Furthermore, the profoundness of the absence of other forms of reflex activity will be found to be the same when there is complete physiological (with or without complete anatomical) interruption of the cord. The problem which remains unanswered therefore is the cause of this sudden and persistent state of depressed reflex activity increasingly profound as one ascends the phylogenetic scale.

Riddoch apparently also accepted the theory that separation of the effector mechanism from cerebral control was the cause of the altered post traumatic reflexes. It seems to us, however, that if the conditions of altered reflex activity were due solely to loss of cerebral direction because of neuronal interruption, the state of change should remain the

same from the time of injury since the interruption once effected is final. It would seem more logical that at least one factor in the appearance of these reflex states would be a change in the intact and adequately vascularized segment of cord and its peripheral nerve and end organs below the level of the lesion of a histological and chemical nature. If that were true it is possible that, during the state of depressed reflex activity the various parts of the reflex arc including the myoneuronal junctions are inactive in a period of reorientation and reorganization of function for a state of autonomous function of a primitive nature. In this state of autonomy however the organs most affected, the muscles do not atrophy apparently because of the viable cord even though connection with the upper motor neuron is lost.

THE STATE OF HEIGHTENED REFLEX ACTIVITY

In our group of 490 patients with spinal cord injury 16.3 per cent were of the cervical cord, 59.6 per cent were of the thoracic cord, and 24.1 per cent were of the conus and cauda equina. Obviously lesions of the cauda equina are not to be discussed with those of the spinal cord when spasm is considered. Sixty-four per cent of the patients suffered injuries of the open type, as bullet, shrapnel or stab wounds of the cord. Thirty-six per cent were patients with closed injuries such as occur in a fracture-dislocation of the spine. A certain number of both types have led to surgical exposure of the lesion either early or late and while we have seen active complete gross anatomical separation of the cord such a state of affairs is the exception rather than the rule even in the severest of either type of injury. The question is always present as to whether the lesion is complete or 'partial'. It seems reasonable to believe that a few remaining shreds of cord tissue are incapable in most instances of remaining viable and of transmitting impulses since such isolated tissue must necessarily suffer secondary softening and degeneration due to pressure or ischemia. We have seen many cords at the level of a fracture-dislocation which appeared slightly contused and swollen while others have been

found in a severe state of crush or even shredded and avulsed but as Naffziger has pointed out if neurological signs do not indicate at the end of 24 hours some viability of the cord or parts of it at the level of the lesion especially by the signs of beginning recovery then most likely no neurological recovery will ever occur. It should be stated here however that since that very question of viability cannot early be determined every opportunity should be afforded to insure the preservation of any such viability by the surgical removal of all causes of local pressure.

It is unfortunate that in neither animals nor man can the complete anatomical and complete physiological lesion be differentiated early. By far the greater number of patients with early complete loss of all neurological function but without gross anatomical section of the cord remain as profoundly and persistently lacking in return of function as do those known to have had the cord actually severed. We have seen little difference in the deep tendon reflexes, plantar responses, muscle spasms genital and viscerovisceral reactions in patients with clean anatomical cord section and those with crush, preservation of continuity of the cord but permanent failure of neurological recovery. Gross anatomical section assures the physiologically complete lesion but a severely contused cord undergoes such softening with later gliosis that it too is in a microscopic sense anatomically severed.

Be the injury cervical or thoracic, open or closed with a complete lesion of the cord as indicated either by surgical verification or by the long persistent failure of recovery the severity of the heightened reflexes varies from patient to patient. There are those patients who never at any time develop anything more than the mildest degree of spasm while others early and rapidly progress to such a condition of hyperactive reflexes that the persistent deformity calls for specific medical or surgical care. It has been our observation that the early care of the patient has much to do with his later period of heightened reflex activity. When the proper surgical care has been given early and when all supportive measures such as early ambulation of the patient, physical therapy proper care of the bladder the avoid-

ance of decubiti and the other sources of sepsis and general debilitation have been attained our patients have been spared later excessive reflex activity and all the attendant ills. The single greatest factor that is under control of those who care for such patients in securing a smooth convalescent course is the avoidance of sepsis especially that which arises from the urinary bladder. Spasm has been greatest in those patients injured in a theater of war where their early care was of ten incomplete and where early a state of sepsis and malnutrition was established. Invariably patients ideally cared for in civilian life have not been found to develop such severe and disabling reflex activity. The incomplete lesion as would be expected produces less severe spasm according to the degree of neurological loss.

The date of onset of the phase of heightened reflex activity is not affected by the severity of the lesion its completeness, or whether it is in a patient with a closed or open wound of the cord. We have seen many patients with incomplete lesions whether verified surgically or by the results of neurological examination and continued observation who developed increased reflex activity as soon as those with complete lesions. In many patients with incomplete lesions recovery will manifest itself within a few hours or days, however and with the appearance of neurological recovery the state of shock must be said to have terminated. Few incomplete lesions show bilaterally symmetrical loss and therefore the resultant state of hyperactive reflexes is seldom the same in the lower extremities. The patient with a completely severed or a hopelessly crushed cord will usually develop the state of heightened reflex activity no sooner or later than the patient with the contused cord which never later shows any neurological function. The date of the surgical treatment if given, regardless of its type, has not been found to affect the date of onset of the heightened reflexes. Patients have been seen who never exhibited any so called spinal shock for more than a few hours with essentially an immediate onset of hyperactive bizarre reflexes (examples one patient with a complete lesion at seventh cervical and another with an incom-

den influx of blood rather than actually erect in the usual sense. We have never observed the emission of semen and upon extensive questioning of the patients we found that it is the exceptional patient who has seen that phenomenon. Occasionally semen like material in small quantity may be seen at the meatus around the catheter or the patient may report that he has seen a quantity of white ropey material in the freshly passed urine. Those few patients admitting masturbation report the failure of any seminal emission. Nocuous stimuli to the erect penis produces a prompt return of the organ to the flaccid state.

It is commonly stated that perspiration does not occur below the level of a complete lesion yet we have many times seen such profuse dripping perspiration over the buttocks and thighs with lesions as high as the fourth thoracic as to be a threat to the development of macerated skin and of decubiti. These same facts were described in detail by Head and Riddoch. We have further observed especially in the upper thoracic lesions that a full bladder just before its automatic evacuation or a bowel distended by an enema, may produce an extensive flush of the body above the lesion headache perhaps nausea, goose-flesh on the skin of the lower extremities and finally on evacuation a return to a normal color of the skin of the face neck and arms with the sudden appearance of beads of sweat over the thighs and trunk (Davis and Martin 1933). Rarely with a lesion at any level have we found the ankles or feet to show more than a minimal amount of perspiration. In many patients these same visceral responses may follow strong stimuli that produce flexor activity such as pricking of the soles of the feet. We have found that after the first 8 or 10 days during which the bowels are usually constipated manipulations of the lower extremities bathing the patient, or changing his position may result in the sudden evacuation of the bowels. As the months wear on however the bowels develop a tendency to either spontaneous evacuation or evacuation after enemas or digital stimulation of the rectum but in any case with a decreasing tendency to take part in the generally heightened reflexes. The

visceral reflexes tire easily more readily than those of the striated muscles, but they are equally sensitive in the resting patient. Given a patient who has been lying quietly in bed without even the stimulation of covers touching his exposed skin the slightest touch on the thigh or groin may cause a spurt of urine, whereas a series of such minimal stimuli are usually necessary to evoke a notable response of the muscles of the lower extremities.

Of the present group of 490 patients, 372 were patients with cord injuries, and 118 with injuries of the cauda equina. Of the 372 80 patients had injuries of the cervical cord, and 292 were patients with thoracic cord injuries. Every one of these 372 patients had during some period of his record some degree of spasm in the lower extremities following the first few days or weeks of decreased reflex activity. By no means was the spasm of such degree as to cause the patient concern or require treatment in all the patients.

In the vast majority of these patients adequate nursing care well directed physical therapy and the maintenance of the general physical well being of the patient (especially by the avoidance of a septic bladder and bed sores) have kept the patients comfortable and allowed them to be sufficiently mobile to permit some mechanical aid to ambulation be it a wheel chair crutches, or braces. The nutritional care of the patient must not be lost sight of in the strenuous program of physical therapy.

The treatment of these patients whose condition demanded relief of the spasm has been either medical or surgical or in some instances, both. In general the use of the common sedatives, as bromides, has not affected the hyperactive reflexes. Curare in its various forms has been used on a considerable number of patients but as yet a prolonged effect and the avoidance of undesirable side effects have not been attained. Posterior rhizotomy as well as the intrathecal injection of alcohol have been used in isolated instances without effect before the patients came under present study. In those patients having been treated by posterior rhizotomy no untoward effects on the skin of the affected segments have been noticed. Anterior rhizotomy as high as the tenth

thoracic inclusive performed in 17 patients has been uniformly successful when applied over a sufficiently great enough number of segments but the operation has been studiously avoided until it was established beyond doubt that the lesion was complete. It has not always been easy to isolate the anterior from the posterior roots at time of operation nor has it always been a simple matter accurately to identify the segments. This is especially true when the injury is at the spinal levels of the eleventh and twelfth thoracic and first lumbar. In 2 patients the scarred proximal and distal ends of the severed cord have been freshly resected with the local removal of all irritating factors, such as abnormal vascular ingrowths, bone fragments, ligamentous cicatrix, and callus, but without prolonged or noticeable effect. Some patients suffering predominantly from adductor spasm and in whom the tendency for the lower extremities to cross has been a real impediment to their otherwise possible ambulation have had immediate relief with an improvement in their use of canes, crutches or braces following the bilateral section of the obturator nerve as approached through the lateral reaches of the space of Retzius. Walking is not interfered with by this procedure which has been performed in 22 patients. There is a smaller group of patients who after months of deformity by severe flexor adductor spasm are not relieved by anterior or posterior rhizotomy because of tendon contractures. These patients are treated by tenotomy at the involved joints.

One may safely assume that Sherrington, Riddoch and even earlier observers believed that the heightened reflex activities of the cord are due to the release of the isolated segment from cortical control and in a sense to the reduction of that isolated segment with the various components of its reflex arcs to a lower phylogenetic status. All these earlier authors are less committal as to the cause of the first stage that of depressed reflex activity. Scarff and Pool have recently shown why they believe that the spasm may be due to local irritation from cicatrix at the level of the lesion. It is certain that a viable cord segment must exist for the full exercise of the reflex arcs

however 'abnormal' the reflexes may appear. But as has been pointed out reflexes of the same severity, persistence and bizarre pattern have been seen in those patients with cords crushed with loss of function and maintenance of gross anatomical continuity as in those with proved complete transection. Furthermore it has not been found that clean surgical resection of the scarred stumps has a favorable effect for more than a few hours or days if at all.

Studies of the isolated cord segments made by us in experimental animals have revealed nothing more significant than the expected degeneration of the descending pathways. What is lacking is our knowledge of the histological alterations in the motor end plates, internuncial neurones, and the sensory nerve endings at the various stages from the time of injury to the time of full development of the hyperactive reflex state. We lack too the knowledge of what certainly must be biochemical changes in these structures especially at the myoneural junction. If it were *only* a matter of release from cerebral control we would not have the good evidence of progressive histological and chemical change in the reflex arc as evidenced by the changes in the reflex state over a period of months.

Riddoch's meticulous and detailed description of his patients indicated his feeling that there is a *constancy* of reactions in both the complete and incomplete lesions. Quite on the contrary this study has emphasized the great variability of the type, date of onset, severity and the characteristics of the altered reflex states from one patient to another. It has not been possible to rely upon any one of the characteristics of the reflexes for purposes of diagnosis or prognosis except to feel that the flexor adductor reaction is characteristic of the complete lesion whereas the extensor response is more often seen in the incomplete lesion, there being frequent exceptions to this loose rule in both instances.

The very facts that certain patients develop extremely little spasm, that some develop it very early and others very late that some show extensor and other flexor responses with the same type of lesion, that the viscerovisceral reflexes are very marked in some pa-

tients and that in some patients the spasm may spontaneously become greatly abated as well as the fact that in the majority of patients sepsis definitely increases the severity of spasm indicate that the adaptability of the isolated cord and its attached peripheral mechanisms to its new independence varies in patient to patient and that this adaptability as indicated in the variety of responses is a matter of intrinsic change anatomical or chemical or both within the various parts of the arc. It is toward a knowledge of these changes that our attentions should be directed rather than solely to the observation and

recording of the dramatic neurological changes demonstrated by physical examination.

ATYPICAL ADYNAMIC ILEUS APPARENTLY CAUSED BY NUTRITIONAL (THIAMINE CHLORIDE) DEFICIENCY

Report of Six Cases

D J LEITHAUSER, M D., F.A.C.S., Detroit, Michigan

DURING the past 5 years, I have observed 4 instances of severe abdominal distention in which the clinical history physical findings and response to therapy strongly suggest that the adynamic ileus was caused by serious nutritional deficiency. These cases brought to mind 2 additional cases observed earlier with similar clinical courses which had not been satisfactorily explained at the time of observation. Review of these 2 case records indicated that they belonged in the same group which may represent a distinct clinical entity of special interest to surgeons since the abdominal distention is so pronounced that acute intestinal obstruction is suspected.

Four patients were chronic alcoholics. In 3 instances celiotomy was performed because of the severe abdominal distention in 2 the condition was erroneously diagnosed as acute appendicitis and in 1—on the basis of obstructive symptoms and the roentgenologist's report—the diagnosis was annular carcinoma of the descending colon. In 1 pronounced distention developed on the fourth day after an operation for inguinal hernia. In the last 2 cases no operation was performed, since the cause of the severe abdominal distention was recognized as nutritional deficiency. Neither of these patients was an alcoholic but the histories revealed that both of them had been on greatly restricted therapeutic diets one for biliary disease, and the other for weight reduction.

CASE 1: A man aged 41 was admitted to Deaconess Evangelical Hospital on March 19, 1942. He was suffering with abdominal distress and distention, diarrhea, pyorrhea, loss of appetite and pains in the calves of his legs. He had had treatment for the diarrhea and pyorrhea for 3 weeks prior to admission without relief and had lost 13 pounds in weight. Careful questioning revealed that the

From St. Joseph Mercy Hospital.

diarrhea consisted of approximately 10 to 15 very small soft stools daily.

Physical examination showed that the patient was emaciated with a waxy pallor, there was a pronounced gingivitis, and considerable abdominal distention. The remainder of the physical examination, including a sigmoidoscopic examination, yielded normal findings. Several examinations of the feces showed no ameba, mucus or blood. The X ray diagnosis was annular carcinoma of the sigmoid.

This diagnosis was questioned since there was no occult blood in the stool. Attempts at decompression with the Wangenstein suction apparatus were made but after 3 days the abdominal distention was not relieved. An exploratory celiotomy revealed pronounced dilatation and engorgement of the descending colon from the splenic flexure to the anus. The colon was thickened and edematous, and the veins were dilated. There was no evidence of tumor constriction or obstruction in any part of the left colon. The cause of this condition could not be determined at the time of operation.

The day after operation extensive palpable rales were present in both lung fields. The mucus was eliminated periodically by coughing in the standing position. The distention which was present before the operation became more pronounced and could not be controlled. By the fifth postoperative day the pyorrhea which had been present previously developed into a severe generalized stomatitis. The patient also developed hallucinations. At that time a more careful inquiry into his past history by questioning a member of the family brought to light the fact that he had been a pronounced alcoholic before the onset of the present illness, although excessive use of alcohol had not been admitted when the routine history was taken. This suggested a vitamin B deficiency as a possible cause of the distention and stomatitis and vitamin B complex was administered orally and parenterally. (However the recommended dosage used at that time is not now considered adequate). During this same period prostigmine was administered intramuscularly several times daily. The response from this drug is immediate, but it produced no appreciable effect on the distention or on intestinal motility. Table I shows the record of the bowel evacuations before and after operation and after the administration of vitamins and prostigmine. The delayed response suggests that it was the vitamin B complex and not the prostigmine that benefited the patient.

This patient's history of distention and diarrhea, with loss of strength and weight, supported a medical diagnosis of cancer which was confirmed by roentgenographic findings interpreted as indicating annular carcinoma of the sigmoid flexure. Since this was the

first case of this type encountered, there was no suspicion that the distention might be related to a nutritional deficiency especially since excessive use of alcohol had been denied. The fact that before the onset of gastrointestinal symptoms the patient had been drinking heavily was not learned until 5 days after the operation.

CASE 2 An Italian, aged 41 on September 21, 1942 was sent to the hospital by his physician because of generalized abdominal distress, which had appeared about 24 hours previously. Examination revealed that the abdomen was grossly distended and tense. The tension was so great that it was impossible to determine the degree of muscular rigidity if any. The blood count showed 9,700 leucocytes, the differential count was 90 per cent polymorphonuclears, 8 per cent lymphocytes, and 2 per cent monocytes.

A provisional diagnosis of ruptured appendix was made, and an exploratory celiotomy was performed. The small bowel was tremendously distended, edematous, and congested, there was no fluid in the peritoneal cavity and the appendix was not readily accessible without producing undue trauma. Therefore an adequate exploration could not be made. The abdomen was closed with a small soft rubber drain in the right pelvis.

After operation the abdominal distention became more intense, despite continuous use of a Wangsten suction apparatus. The patient became irrational with muttering delirium periodically, and had to be restrained. There was no evidence of infection, since the temperature did not rise above 100 degrees F. there was no drainage from the wound and a small soft stool was evacuated. No attempt was made to institute ambulation because of the tremendous abdominal distention and serious morbidity of the patient. However in-bed exercises (contraction of voluntary muscles) were carried out systematically between periods of delirium.

In view of the similarity of the clinical picture to that which had been observed previously in Case 1 a more thorough investigation was made on the second postoperative day in regard to the patient's consumption of alcohol. Although, when the history had been taken originally he had stated that he drank only moderately specific inquiry as to the amount consumed indicated that he had been disposing of several quarts of red wine a week, a case of beer each week-end and some whiskey daily for a period of several years. These data furnished a basis for suspecting a nutritional deficiency and thiamine chloride (30 mgm.) 1 ampole of vitamin B complex, and 100 milligrams of ascorbic acid were administered parenterally along with proctigmine.

Some improvement was evident the following day. The patient passed some flatus, but the distention did not decrease materially until 48 hours after the administration of the thiamine chloride, other vita-

mins and prostigmine. He then became ambulatory and improvement was rapid. (Since as in Case 1 the response was gradual rather than immediate it seems probable that relief of the distention cannot be attributed to the prostigmine which at first was administered every 2 hours for 2 doses and there after in a dosage of 1 ampule daily.) By the fourth postoperative day, the distention was almost completely relieved, the patient became rational and his general improvement was striking. There was no discharge from the wound and the drain was removed. He was discharged, ambulatory on the eighth postoperative day and his general condition continued to improve.

This case recalled the experience described in Case 1. The presence of uncontrollable distention in this instance led to the suspicion of a nutritional deficiency, and this was substantiated by eliciting a definite history of alcoholism. Since the appendix was not removed and there were no discharge through the drain and no later evidence of a localized abscess and since the patient recovered completely and has remained well it would seem probable that the nutritional deficiency accounted for both the preoperative and postoperative distention.

CASE 3 An Italian aged 64, with a typical beer belly type of obesity, drank approximately 1 case of beer every week and about 2 glasses of wine daily. He had been well until 3 weeks before admission when he developed a left inguinal hernia.

The patient was advised to discontinue taking alcohol for 1 week, and then a herniorrhaphy was performed. He was ambulatory after operation. Pronounced abdominal distress and distention developed on the second postoperative day and Wangersten suction was instituted. This afforded some relief but the distention could not be adequately controlled. The patient was out of bed at frequent intervals for coughing, and expectorated some mucus on these occasions for several days. Decompression was discontinued on the sixth postoperative day and the patient began to take some nourishment. He improved gradually and was dismissed on the twelfth day after operation.

Although this patient was observed in January, 1942 before the experience with Cases 1 and 2 and hence vitamin deficiency was not suspected it seems probable that the severe postoperative distention in this instance was due to a nutritional deficiency secondary to chronic alcoholism. With ambulatory treatment and other supportive measures the condition was brought under control. Several months later vitamin B complex was

prescribed for this patient with considerable improvement in his general health.

CASE 4 A man aged 52 was admitted to the hospital on January 7, 1938 with a diagnosis of acute appendicitis. He had been well until 4 days previously when he developed abdominal discomfort and distention, with tenderness over the right lower quadrant. The patient took a laxative, which initiated a diarrhea. On previous occasions he had also had frequent small soft stools. He finally consulted a physician who advised hospitalization and operation. On examination the abdomen was considerably distended and tympanitic there were no masses or scars but there was tenderness over the right lower quadrant.

Appendectomy was performed by my associate. The appendix was retrocolic, bound down with very dense adhesions and was removed with considerable difficulty because of the distention. A small soft rubber drain was inserted. Pathologic examination of the appendix showed catarrhal changes, edema and congestion, evidently not the cause of the patient's complaint.

After operation abdominal distention became pronounced, and Wangersten suction was instituted. The patient was irritable, restless and complained of abdominal distress. Parenteral fluids were administered as indicated. However he became increasingly restless, irrational and eventually violently delirious (typical alcoholic delirium). Abdominal distention could not be controlled at any time by decompression.

After the appearance of the typical delirium tremens members of the family admitted that the patient had been a chronic alcoholic for years. Since this patient was treated before early ambulation was routinely used in the management of surgical cases, he was placed in shackles to keep him in bed (Out-of-bed exercises, however, probably would have been helpful.) His clinical course was steadily downward with progression of abdominal distention to paralytic ileus, increasing delirium and finally death.

At autopsy, there was gross abdominal distention, but careful dissection of the operative field showed that the operation was ideal from the standpoint of surgical and gross anatomical pathology. The pathologist's diagnosis was adynamic paralytic ileus, early portal cirrhosis of the liver, terminal hypostatic pneumonia.

This case was observed several years before Cases 1 and 2 and before early ambulation was used routinely. It was not suspected at that time that a nutritional deficiency played any part in causing the adynamic ileus. After the experience with the other patients, however, this case was recalled and reviewed and it would appear in retrospect that this patient belongs in the same group. The diarrhea and

distention before operation the anomalous findings in the appendix the uncontrollable distention and delirium after operation the history of alcoholism and postmortem evidence of liver damage all point to this conclusion. If this entity had been recognized at that time in all probability no surgery would have been performed in case operation had been performed if present methods of management had been used—that is early ambulation and administration of thiamine chloride—it seems probable that the fatal outcome might have been averted.

CASE 5 A woman aged 33 was admitted to the hospital on November 3, 1943. For about a year before she had been having attacks of epigastric abdominal pain which occurred at irregular intervals and had been relieved by codeine. Before the onset of these attacks, her diet had been varied and well balanced. Five months before admission, her physician made a diagnosis of biliary colic and advised her to go on a diet excluding meat, almost all vegetables, all highly seasoned food, butter, gravy, fats and coffee. Her diet was limited chiefly to toast, tea, milk and ice cream. The only other foods she ate were carrots, pie, cake, cookies, apples and pears. After about 5 months on this regimen she had an attack of abdominal distress and ate very little during the following week. During this period abdominal distention developed, and the patient was hospitalized. Wangensten suction with the Levine tube was instituted and she received glucose in normal saline solution parenterally. For the following 15 days, she was unable to take food. Despite the Wangensten suction and use of enemas, the abdominal distention increased; this was associated with much discomfort, but no pain. She passed small soft stools nearly every time she urinated (about four or five times a day).

The roentgenologic findings were atypical, and the roentgenologist's opinion was somewhat indefinite and inconclusive. On November 12, 10 days after admission the report was as follows: "The examination of the stomach reveals a mottling or nodulation of the barium within the stomach as a result of a large amount of fluid. The same condition is found in the small intestines. The barium passed through the esophagus without visualizing any abnormality. The stomach was fish-hook in formation and hypotonic in fact, atonic. A large amount of fluid is within the stomach and the patient has tenderness above and medial in the epigastrium. The duodenal bulb showed a normal contour. There was practically complete retention at 5 hours. The barium enema passed through the whole length of the colon without visualizing any evidence suggestive of obstruction or neoplasm. A large amount of barium passed through the ileocecal valve and

we note that there is also some barium within the stomach at 24 hours. Conclusions: The patient apparently has a gastric ulcer close to the pylorus with evidence of gastritis. A supplementary report will follow later."

Following is the verbatim report of the supplementary study on November 15:

"The review of the films and further study of the gastrointestinal tract would suggest the following: On the films we note a crater close to the pyloric end of the stomach which we believe is due to a duodenal ulcer. But we are not able from the films, to account for the retention of the stomach at 5 hours and 24 hours, and would suspect that there would be an obstruction at the pylorus or duodenum. But we fail to find a definite obstruction. We also note that the small intestines are distended in fact, over distended suggesting the possibility of obstruction in the terminal ileum. But it was impossible to get a very good visualization of the small intestines. On the large intestines we note that there is no distention and that the descending colon is rather spastic. There is also irritability of the transverse colon. Summing up the case, one would be suspicious that there may be an obstruction at the terminal ileum or that this may be a metabolic disturbance similar to a dietary deficiency. Still I am not able to get away from a possible organic lesion in the terminal ileum."

Two days after this second roentgenologic report (November 17) I was called in consultation to consider the advisability of surgical intervention since the physician assumed that the condition was due to intestinal obstruction even though the roentgenologist had mentioned the possibility of a nutritional deficiency. After a more careful and complete history was obtained which along with the pronounced intestinal distention, distress but no pain, and several small soft stools daily, presented a picture similar to that of Case 1, a diagnosis of vitamin deficiency was made. At that time, the serum albumin was 3.2 and the serum globulin 4.6.

Treatment for the nutritional deficiency was instituted immediately. This consisted of thiamine chloride 100 milligrams intravenously, 1 ampule of solu B, intramuscularly, and amino acids, intravenously. A siphon suction unit (12) with the Cantor tube (3) was introduced for intestinal decompression. This was removed 2 days later when another roentgenologic study revealed no evidence of any mucous distention anywhere in the gastrointestinal tract, either in the flat or upright films.

Five days after treatment was instituted, the patient's condition was greatly improved; distention had disappeared, there was no vomiting, she tolerated food well and was ambulatory. The serum albumin was 3.6 and the serum globulin 2.9. The patient left the hospital 10 days after vitamin therapy was started (November 28) completely well. She received detailed instruction regarding a high-vitamin, high-protein diet. She has followed this and has had no recurrence of symptoms.

In this instance although the patient was referred for surgical treatment for a supposed intestinal obstruction, the cause of the symptoms was recognized as nutritional deficiency which had produced an adynamic ileus and no operation was performed. The patient's response to thiamine chloride and protein therapy was striking, and with correction of her diet, she has remained completely well.

CASE 6. A man aged 53 consulted his physician for an annual health examination. He had complained of no illness but was overweight. After a complete examination including an electrocardiogram and roentgenologic study of the gastrointestinal tract and gall bladder and a sigmoidoscopic examination, all of which yielded normal findings, his physician recommended a restricted diet for weight reduction. The patient followed this diet for several weeks, but was not satisfied with the rate of weight loss and so restricted his diet to the following: breakfast—1 slice toast, orange or grapefruit; black coffee; luncheon—meat, fresh fruit; dinner—meat, vegetables including only lettuce, spinach, carrots, and peas and canned fruit.

On this diet which was extremely deficient in variety, he lost approximately 20 pounds in 2 months. During this period he tired easily and felt exhausted most of the time. He felt that he was not so keen mentally, was irritable and suffered from pains in the calves of the legs. His abdomen became bloated and distended and bowel evacuations occurred two or three times a day but these did not relieve the distention. Finally the distention increased enormously and respiration was embarrassed at this point the patient became alarmed and consulted me. Except for the tremendous abdominal distention, physical examination revealed nothing abnormal. Although the patient complained of considerable distress there was no belching, passing of flatus or actual pain. Since a health examination including a complete gastrointestinal and gall-bladder roentgenologic study and a sigmoidoscopic examination had recently been made it was concluded that this patient was suffering from an acute adynamic ileus on a nutritional basis (thiamine deficiency). Thiamine chloride 100 milligrams was administered and repeated in 4 hours; this regimen produced complete relief in 12 hours. The injections were continued daily for several days and the nervous symptoms, leg pains and irritability disappeared completely. Bowel evacuations decreased to one a day. The patient received dietary instruction and therapeutic doses of vitamin B complex orally. His general health has remained excellent, with no recurrence of gastrointestinal symptoms. The patient says that he feels by far more alert and has never been more fit in his life.

In this instance as in Case 5 the cause of the severe abdominal distention was recog-

nized after a dietary history was obtained. Response to administration of thiamine chloride was prompt and spectacular.

DISCUSSION

Despite the enormous number of clinical and experimental studies on nutritional deficiencies that have been reported during the last few decades and the increasing precision of knowledge concerning them it would appear that numerous clinical problems associated with these disorders remain to be elucidated. So far as could be ascertained by a search of the *Quarterly Cumulative Index Medicus* for the past several years the exact clinical syndrome here described has not been previously reported even though the recognition of digestive symptoms as a phase of vitamin B deficiency has been well established clinically and roentgenologically (5, 9, 19). In previous reports however there has been no emphasis on the fact that severe and uncontrollable abdominal distention¹ which might lead to erroneous surgical diagnoses and needless operations may be the result of vitamin B deficiency.

The roentgenologic studies made by Golden (5, 6, 13) have stimulated interest in the relationship of vitamin deficiency to intestinal motility (1, 2, 7, 8, 10, 15, 18) and the so called deficiency pattern of the small intestine is a fairly well defined radiologic entity. However, as Golden (5) has emphasized the roentgenologic findings are not constant and appear to vary with the severity and duration of the nutritional disorder. In earlier less advanced stages the barium passes rapidly through the jejunum reaching the lower part of the small intestine in 15 minutes and entering the cecum in less than half an hour; the lumen is reduced to one-half or even one-fourth its normal width. In more advanced stages movement of barium through the intestine is slow and

In retrospect, it is my impression and that of numerous surgeons with whom I have discussed the problem, that immediately after the first World War abdominal distention and adynamic ileus were much more common and troublesome complications in surgical cases than they have been in recent years. In fact, it was to meet this problem that the Wangensteen suction apparatus for decompression of the intestinal tract was developed. Although undoubtedly some of the decreased incidence of adynamic ileus can be attributed to more general use of mechanical decompression and improved surgical technique, it is possible also that it is due in part to improved nutrition and the widespread use of supplementary vitamins by the general public.

the lumen may vary from normal to more than twice normal width. Dilated loops are characteristically seen in well advanced stages which are usually designated clinically as non-tropical sprue. There is abnormal segmentation owing to areas of spasm of variable length sometimes completely expelling the opaque material from the contracted area giving the impression of a discrete mass. A scattering effect may be caused by small irregular masses of barium left behind as the main mass of barium passes along. In more advanced stages, gas and fluid levels on plain abdominal roentgenograms may suggest the possibility of ileus. The most marked and persistent changes are localized in the middle third of the small bowel.

Not all patients with clinically diagnosed vitamin B deficiency show the roentgenologic changes in the intestine and conversely the typical roentgenologic changes have been observed in patients in whom vitamin B deficiency was not confirmed clinically (15). Disturbances of the digestive tract associated with vitamin B deficiency cause a variety of symptoms, so the clinical picture is not constant. The main features of the syndrome described by Lepore and Golden are malnutrition, a flat oral dextrose tolerance curve, an abnormal roentgenologic pattern in the small intestine and gastrointestinal symptoms including flatulence, pain, diarrhea (in 25 per cent) and constipation. (In this series malnutrition was a prominent feature only in Case 1.) Brown and Trowell have reported a syndrome they have seen in Polish refugees and in African and Indian adults and children in which the roentgenologic picture is similar to that described by Golden and the symptoms suggestive of pyloric obstruction. In their cases great gaseous distention of the colon was common. This syndrome responds to administration of whole vitamin B complex. Heilig has reported that a high percentage of hospital beds in Mysore, India, are occupied by patients, mostly young or middle-aged women with chronic diarrhea of a few weeks to 2 years duration. After the exclusion of true dysenteries, a certain group have glossitis, loose stools 5 to 8 times daily containing substantial amounts of mucus and

starch granules but no fat. In cases of long standing symptoms of colitis become prominent. Hypochromic anemia belongs with this condition, increasing with duration. None of the patients showed typical signs of pellagra and none had fatty stools of sprue-like character. Nevertheless many responded surprisingly quickly to nicotinic acid although refractory to routine treatment.

These few reports are cited to show that the digestive symptoms accompanying vitamin B deficiencies are not constant, and may manifest themselves in various syndromes. Numerous extrinsic and intrinsic factors apparently account for this variability which is dependent both on the lack of particular food factors, individually or in combination, and the duration of the deficiency and on individual metabolic differences in ability to utilize them which in turn are influenced by various acute and chronic diseases. As Kiefer has stated, vitamin deficiencies particularly those involving the vitamin B complex group of vitamins can profoundly impair digestion and absorption of essential food elements, including carbohydrate, protein and fat. Since malabsorption further diminishes the subject's vitamin intake, a vicious circle is established." In sprue and related conditions—such as Herter's infantism, Gee's disease and idiopathic steatorrhea—the basic disturbances apparently are related to fat metabolism. In the syndrome described by Heilig the basic disturbance apparently was related to utilization of carbohydrate. In at least one of the cases reported here (Case 5) there was evidence of a disturbance in protein metabolism. These facts indicate that the metabolism of any or all of the essential food materials may be impaired by vitamin B deficiency since all these conditions respond to administration of vitamin B complex or one of its components.

As Golden (5, 6) has pointed out, the intramural nervous system is the most probable medium through which nutritional deficiency affects the intestinal tract. Essentially the same type of radiologic pattern of the intestines as that found in well advanced deficiency states is present in normal newborn infants, which, after 3 or 4 months is replaced

by the usual adult pattern. This change is probably due to evolution of the incompletely developed nervous control of the intestine.

Experimentally, it has been demonstrated (17) that cholinergic nerves liberate not only acetyl choline but also thiamine, when stimulated and that thiamine increases the effect of acetyl choline on the intestine and circulatory apparatus of the cat. Chemically acetyl choline and thiamine chloride are closely related compounds and hence may function synergistically. It seems probable that these facts furnish clues as to the mechanism of production of adynamic ileus in the presence of thiamine deficiency and as to the striking therapeutic response to administration of thiamine chloride parenterally.

In the cases in this series the characteristic pathologic changes encountered were edema and thickening of the intestinal walls with engorgement of the blood vessels. In fatal cases of deficiency disease in which roentgenologic changes have previously been demonstrated in the intestine atrophy of the tunica muscularis and mucosa, edema, round cell infiltration and fibrosis of the submucosa and ulceration have been described (5).

The type of pathologic changes in the intestine and the variety of gastrointestinal symptoms that have been described in deficiency states suggest that it would be wise to suspect a nutritional disturbance in any case in which the digestive symptoms, clinical and radiologic findings seem atypical or anomalous. It might be in this way that the etiology of certain obscure gastrointestinal conditions might be elucidated. It may even be justifiable to raise the question whether nutritional deficiency may play a rôle in the causation of at least some cases of so called nonspecific regional enteritis especially in view of Owen's (14) recent pathologic study, which showed neuromuscular hyperplasia as a characteristic feature of this condition, not previously reported by others.

Owing to the unscientific and unscrupulous propaganda and advertising concerning vitamins by certain drug manufacturers, many medical men have taken an extremely cautious attitude toward the use of vitamins, and hesitate to designate any condition as caused by

nutritional deficiency unless the characteristic lesions of well advanced stages of the deficiency are present. This attitude seems scarcely justifiable in the present state of our knowledge concerning these conditions because of the variability of the manifestations in so called *subclinical deficiency states* and the constant descriptions of 'atypical syndromes' responding to vitamin and nutritional therapy.

In the absence of the so called characteristic lesions the response to therapy must be accepted as significant evidence that a nutritional disturbance is the cause of particular symptoms. Of the patients here described whose symptoms of adynamic ileus were dramatically relieved by administration of thiamine chloride and vitamin B complex, only one (Case 1) had the characteristic stomatitis of vitamin B deficiency; furthermore stool examinations in 2 cases failed to reveal any evidence of steatorrhea which is characteristic of the advanced vitamin B deficiency known as the sprue syndrome.

It may be that the syndrome here described is more likely to occur in patients who have some liver damage. This supposition is strengthened by the facts that it has been demonstrated that thiamine deficiency is more frequent in patients with liver disease (4), and that 4 of the 6 patients were chronic alcoholics, another was obese and the sixth patient was under treatment for biliary disease.

The history is probably the best clinical guide in making a preliminary diagnosis of dietary deficiency—although the original history obtained may often be misleading. Few persons who drink large quantities of alcoholic beverages believe that they imbibe to excess so an alcoholic history may be difficult to obtain unless specific questions are asked to elicit this information. Dietary idiosyncrasies also are not reported voluntarily since patients who have them regard them as normal. Hence whenever a nutritional deficiency is suspected a careful dietary history must be taken. As Spies has found nutritional deficiencies are to be suspected in persons whose diets have been inadequate in persons whose utilization and absorption of nutrients seem impaired in chronic alcoholics and in those with dietary idiosyncrasies.

the lumen may vary from normal to more than twice normal width. Dilated loops are characteristically seen in well advanced stages which are usually designated clinically as non-tropical sprue. There is abnormal segmentation owing to areas of spasm of variable length sometimes completely expelling the opaque material from the contracted area, giving the impression of a discrete mass. A scattering effect may be caused by small irregular masses of barium left behind as the main mass of barium passes along. In more advanced stages, gas and fluid levels on plain abdominal roentgenograms may suggest the possibility of ileus. The most marked and persistent changes are localized in the middle third of the small bowel.

Not all patients with clinically diagnosed vitamin B deficiency show the roentgenologic changes in the intestine and conversely the typical roentgenologic changes have been observed in patients in whom vitamin B deficiency was not confirmed clinically (15). Disturbances of the digestive tract associated with vitamin B deficiency cause a variety of symptoms so the clinical picture is not constant. The main features of the syndrome described by Lepore and Golden are malnutrition, a flat oral dextrose tolerance curve, an abnormal roentgenologic pattern in the small intestine and gastrointestinal symptoms including flatulence, pain, diarrhea (in 25 per cent) and constipation. (In this series malnutrition was a prominent feature only in Case 1.) Brown and Trowell have reported a syndrome they have seen in Polish refugees and in African and Indian adults and children in which the roentgenologic picture is similar to that described by Golden and the symptoms suggestive of pyloric obstruction. In their cases, great gaseous distention of the colon was common. This syndrome responds to administration of whole vitamin B complex. Heilig has reported that a high percentage of hospital beds in Mysore, India, are occupied by patients, mostly young or middle-aged women with chronic diarrhea of a few weeks to 2 years' duration. After the exclusion of true dysenteries, a certain group have glomeritis, loose stools 5 to 8 times daily containing substantial amounts of mucus and

starch granules but no fat. In cases of long standing symptoms of colitis become prominent. Hypochromic anemia belongs with this condition increasing with duration. None of the patients showed typical signs of pellagra and none had fatty stools of sprue-like character. Nevertheless, many responded surprisingly quickly to nicotinic acid, although refractory to routine treatment.

These few reports are cited to show that the digestive symptoms accompanying vitamin B deficiencies are not constant, and may manifest themselves in various syndromes. Numerous extrinsic and intrinsic factors apparently account for this variability which is dependent both on the lack of particular food factors individually or in combination, and the duration of the deficiency and on individual metabolic differences in ability to utilize them which in turn are influenced by various acute and chronic diseases. As Kleider has stated, vitamin deficiencies, particularly those involving the vitamin B complex group of vitamins, can profoundly impair digestion and absorption of essential food elements, including carbohydrate, protein and fat. Since malabsorption further diminishes the subject's vitamin intake, a vicious circle is established. In sprue and related conditions—such as Herter's infantile atrophic disease and idiopathic steatorrhea—the basic disturbances apparently are related to fat metabolism. In the syndrome described by Heilig, the basic disturbance apparently was related to utilization of carbohydrate. In at least one of the cases reported here (Case 5) there was evidence of a disturbance in protein metabolism. These facts indicate that the metabolism of any or all of the essential food materials may be impaired by vitamin B deficiency since all these conditions respond to administration of vitamin B complex or one of its components.

As Golden (5, 6) has pointed out, the intramural nervous system is the most probable medium through which nutritional deficiency affects the intestinal tract. Essentially the same type of radiologic pattern of the intestines as that found in well advanced deficiency states is present in normal newborn infants which after 3 or 4 months is replaced

by the usual adult pattern. This change is probably due to evolution of the incompletely developed nervous control of the intestine.

Experimentally it has been demonstrated (17) that cholinergic nerves liberate not only acetyl choline but also thiamine when stimulated and that thiamine increases the effect of acetyl choline on the intestine and circulatory apparatus of the cat. Chemically acetyl choline and thiamine chloride are closely related compounds and hence may function synergistically. It seems probable that these facts furnish clues as to the mechanism of production of adynamic ileus in the presence of thiamine deficiency and as to the striking therapeutic response to administration of thiamine chloride parenterally.

In the cases in this series the characteristic pathologic changes encountered were edema and thickening of the intestinal walls with engorgement of the blood vessels. In fatal cases of deficiency disease in which roentgenologic changes have previously been demonstrated in the intestine atrophy of the tunica muscularis and mucosa edema round cell infiltration and fibrosis of the submucosa and ulceration have been described (5).

The type of pathologic changes in the intestine, and the variety of gastrointestinal symptoms that have been described in deficiency states, suggest that it would be wise to suspect a nutritional disturbance in any case in which the digestive symptoms clinical and radiologic findings seem atypical or anomalous. It might be in this way that the etiology of certain obscure gastrointestinal conditions might be elucidated. It may even be justifiable to raise the question whether nutritional deficiency may play a rôle in the causation of at least some cases of so called nonspecific regional enteritis especially in view of Owen's (14) recent pathologic study, which showed neuromuscular hyperplasia as a characteristic feature of this condition not previously reported by others.

Owing to the unscientific and unscrupulous propaganda and advertising concerning vitamins by certain drug manufacturers many medical men have taken an extremely cautious attitude toward the use of vitamins and hesitate to designate any condition as caused by

nutritional deficiency unless the characteristic lesions of well advanced stages of the deficiency are present. This attitude seems scarcely justifiable in the present state of our knowledge concerning these conditions because of the variability of the manifestations in so called subclinical deficiency states and the constant descriptions of atypical syndromes responding to vitamin and nutritional therapy.

In the absence of the so called characteristic lesions the response to therapy must be accepted as significant evidence that a nutritional disturbance is the cause of particular symptoms. Of the patients here described whose symptoms of adynamic ileus were dramatically relieved by administration of thiamine chloride and vitamin B complex only one (Case 1) had the characteristic stomatitis of vitamin B deficiency furthermore stool examinations in 2 cases failed to reveal any evidence of steatorrhea, which is characteristic of the advanced vitamin B deficiency known as the sprue syndrome.

It may be that the syndrome here described is more likely to occur in patients who have some liver damage. This supposition is strengthened by the facts that it has been demonstrated that thiamine deficiency is more frequent in patients with liver disease (4), and that 4 of the 6 patients were chronic alcoholics another was obese and the sixth patient was under treatment for biliary disease.

The history is probably the best clinical guide in making a preliminary diagnosis of dietary deficiency—although the original history obtained may often be misleading. Few persons who drink large quantities of alcoholic beverages believe that they inhibit to excess so an alcoholic history may be difficult to obtain unless specific questions are asked to elicit this information. Dietary idiosyncrasies also are not reported voluntarily since patients who have them regard them as normal. Hence whenever a nutritional deficiency is suspected a careful dietary history must be taken. As Spies has found nutritional deficiencies are to be suspected in persons whose diets have been inadequate in persons whose utilization and absorption of nutrients seem impaired in chronic alcoholics, and in those with dietary idiosyncrasies.

SUMMARY

The cases of 6 patients with adynamic ileus with severe abdominal distention are reported to call attention to the fact that symptoms suggesting the presence of intestinal obstruction and leading to erroneous diagnoses and unnecessary operations may be caused by thiamine chloride deficiency. In these cases the distention was not controlled by mechanical decompression or administration of prostigmine but responded dramatically to administration of thiamine chloride and vitamin B complex.

In the first case in which the condition was recognized as resulting from vitamin deficiency the patient had a sore mouth which directed attention to this possibility, and specific questions brought to light a history of chronic alcoholism. In this instance a preoperative diagnosis of annular carcinoma of the sigmoid had been made on the basis of obstructive symptoms and the roentgenographic findings but no such lesion was found at operation. However the abdominal distention increased after operation and was not brought under control until vitamin therapy was instituted. The second patient, also an alcoholic, was subjected to celiotomy for acute appendicitis but at operation there was so much intestinal distention that the appendix was not readily accessible and was not removed. When uncontrollable distention continued after operation the experience in the first case was recalled, and vitamin therapy was instituted with equally striking results.

These 2 cases brought to mind 2 earlier cases of severe adynamic ileus of the same type and review of these records confirmed this impression since both of the patients were alcoholics. In one celiotomy was performed because of a mistaken diagnosis of acute appendicitis but no pathologic evidence was found in the appendix to account for the symptoms. Adynamic ileus progressed after operation with severe alcoholic delirium to a fatal outcome. The fourth patient had developed severe distention after an inguinal herniorrhaphy but this patient recovered without the administration of thiamine chloride.

The last 2 patients were not alcoholics, but had been on greatly restricted diets—in one instance for biliary disease, and in the other for weight reduction. In these cases, no operation was performed since nutritional deficiency was recognized as the cause of the distention and response to administration of thiamine chloride and vitamin B complex was striking and complete.

This experience suggests that nutritional deficiency should be suspected and a therapeutic trial of vitamins made in cases of abdominal distention in which the evidence does not justify a positive diagnosis of mechanical obstruction of the intestines. It suggests also that thiamine chloride should be administered at the time of operation to prevent postoperative distention, especially in patients whose nutritional status is at all questionable or in whom there is any suspicion of liver damage.

It is now my routine practice to administer parenterally vitamin B complex with high thiamine content to all surgical patients the day before operation and daily for 3 days after operation. Since this has been done, postoperative distention has been almost entirely eliminated.

OBSERVATIONS ON THE USE OF GELATIN SPONGE IN CLOSURE OF EXPERIMENTALLY PRODUCED DEFECTS OF THE BRONCHUS

C. ROLLINS HANLON M.D., Baltimore, Maryland

HEALING of the bronchial stump is recognized as the most important factor in successful pulmonary resection. Rienhoff, Gannon, and Sherman have stressed the importance of healing at the end of the bronchus and have shown that satisfactory closure may be achieved in the dog by airtight approximation of the pleura overlying the bronchial stump. Tafel has shown that airtight closure of tracheal and bronchial defects by patching with free fascial grafts is associated with uniformly successful healing in the dog. The graft acts as a non-viable scaffolding around which the fibroblasts and mucosal cells rapidly reconstruct a new tracheobronchial segment.

Since the primary problem is one of temporary airtight closure while natural reparative processes are at work, the use of an absorbable material for sealing bronchial defects seems logical. The successful use of absorbable agents for hemostasis has now become commonplace.⁽⁴⁾ With such a background, absorbable gelatin sponge has been used during this study in the closure of various defects in the bronchial tree of the dog.

The behavior of gelatin sponge in living tissues has been intensively studied.^(2, 5) Its physical properties have been determined also, but I am aware of no published data on its behavior when used as a barrier to the passage of air. Preliminary *in vitro* experiments showed that moist gelatin sponge was surprisingly resistant to the passage of air. It seemed probable that this material, if it could be kept apposed to an opening in the bronchus, would act as a suitable seal to prevent leakage of air. The procedures outlined in this study were designed to test this hypothesis in the living animal.

From the Department of Surgery of the Johns Hopkins University and the Johns Hopkins Hospital.

METHODS

Mongrel dogs were used, varying in weight from 6 to 17 kilograms, with the average below 10 kilograms. Diet consisted of dog biscuit and water. Procedures were conducted under endotracheal ether anesthesia, the lungs being inflated rhythmically by a machine while the pleural cavity was open. Silk technique was employed throughout.

The gelatin sponge used was identical with that available commercially in strips 60 by 20 by 7 millimeters. It was prepared for use by moistening in normal saline solution and expressing the excess fluid before application as a patch. In no instance were sutures used to hold the material in position, reliance being placed solely on the action of the surrounding structures and the inherent adhesiveness of the material when moistened with saline and placed in contact with body fluids.

Four groups of experiments were conducted:

1. Test of ability of the material to resist passage of air *in vitro*.
2. Partial transection of the bronchus to the left diaphragmatic lobe and covering the defect with gelatin sponge.
3. Removal of a small segment from the ventral wall of the bronchus to the left diaphragmatic lobe and covering the defect with gelatin sponge.
4. Excision of the upper lobe of the left lung and covering the open end of the bronchial stump with gelatin sponge.

All animal experiments were controlled by production of similar lesions not sealed by gelatin sponge. The operative areas were examined bronchoscopically on many occasions. After certain periods had elapsed the animals were killed by an overdose of anesthetic agent. Water was poured into the opened chest and the lungs were slowly inflated to a point where leakage of air occurred either from the opera-

tive area or from the normal lung parenchyma. Sections of all lesions were examined microscopically.

1 In vitro experiments Commercial gelatin sponge of standard size (60 by 20 by 7 mm.) was moistened with normal saline solution, the material was compressed between the fingers to express the fluid and then tied over the end of a glass tube in the fashion of a drumhead. With the covered end of the tube held under water gradually increasing air pressure was applied within the tube until air escaped through the gelatin sponge.

The tubing used was of three sizes 3, 4, and 7 millimeters inside diameter. With larger tubing it was difficult to secure an airtight seal when using the standard sized gelatin sponge. This material shrinks about 15 per cent on being treated in the manner described.

There seemed to be no constant relation between size of the tubing and the pressure at which leakage occurred. The average pressure required was 40 millimeters of mercury with extremes of 18 and 80 millimeters of mercury in the 15 samples tested. These variations appear to be at least partially related to inequalities in the pores of the gelatin sponge. An unusually large bubble in the material at the site of testing may reduce its thickness in the dry state from 7 millimeters to less than 3 millimeters, and such a thin area might be expected to transmit air at a lower pressure.

When leakage began it would continue despite reduction in pressure. Complete release of pressure and retesting after a short interval however gave values as high as or occasionally higher than the original figure. A variety of *in vitro* tests (such as behavior when moistened with serum or blood) suggest themselves but these points have not yet been investigated.

2 Partial section of bronchus to left diaphragmatic lobe The left chest was entered through the fifth intercostal space exposing the bronchus to the left diaphragmatic lobe. This was separated from the artery and a strip of moistened gelatin sponge placed behind it (Fig. 1). A transverse incision was then made through the ventral half of the bronchus which gaped widely (Fig. 2). The two ends of the gelatin sponge were overlapped to cover this defect. Pressure was applied for about 15 seconds un-

til the ends of the gelatin sponge became adherent by virtue of the blood which was lost on section of the bronchus. The nearby pulmonary artery also played an important rôle in maintaining the position of the material (Fig. 3). No sutures were used. The chest was closed in the usual manner excess air being aspirated through an intercostal catheter which was withdrawn before closure of the skin.

Ten animals were treated in this fashion and all survived without complication until killed under anesthesia at from 1 to 10 weeks.

Three dogs were used as controls. The first of these had undergone a left thoracotomy for another purpose some weeks previously and there were many pleural adhesions. With a knife a 6 millimeter transverse slit was made in the ventral wall of the bronchus to the left diaphragmatic lobe, which gaped very slightly. No gelatin sponge was placed but continuous aspiration of the pleural space was employed during closure and at frequent intervals in the ensuing hour. The animal required no further treatment and remained well until death from another cause a month later. Two animals treated with a slightly more extensive partial bronchial section without gelatin sponge died promptly despite intensive aspiration.

In the first instance it seems likely that aspiration prevented development of a fatal tension pneumothorax until adjacent pulmonary tissue sealed the bronchial opening. Adhesions from the previous thoracotomy may have exerted a favorable effect by preventing the customary gaping of what was admittedly an unusually small bronchial wound.

The microscopic appearance of the repaired bronchus in animals killed at varying intervals after operation confirms previous studies on the healing of tracheobronchial defects. Proliferation of mucosal cells occurred rapidly and a complete but thin epithelial covering might be present in as little as 2 weeks. The meshes of the gelatin sponge were filled with red blood cells in the early stages. These were gradually replaced by macrophages which invaded the periphery and slowly removed the sponge.

In general absorption of gelatin sponge from around the bronchus was slow in comparison with its rate of disappearance when im-

Fig. 1 Showing separation of the pulmonary artery from the bronchus to the left diaphragmatic lobe. A strip of moistened gelatin sponge is being placed behind the bronchus.

Fig. 2 With gelatin sponge in place a transverse slit has been made in the ventral wall of the bronchus to the left diaphragmatic lobe. Insert shows the larger opening after removal of a wedge from the bronchus.

planted in such tissues as omentum or muscle. The structure of the material could still be seen in some specimens 60 days after operation although in other animals it was absorbed much more rapidly. There was ordinarily a minimal polymorphonuclear cell reaction. Sections showed the sponge acting as a plug in the defect while mucosa grew over its internal surface and fibrous tissue invaded its meshes to reform the bronchial wall.

A typical result is seen in the accompanying photomicrograph (Fig. 4a) showing that the gelatin sponge has covered the defect and fitted snugly into the space between the divided bronchial cartilages. In a view under higher magnification (Fig. 4b) one can see beginning epithelial growth at the margins but the gelatin sponge has not been covered after 1 week.

3 Excision of bronchial segment Because of the survival of 1 control dog in the previous group it seemed that mere partial division of the bronchus was not a sufficiently severe test of the method. A second series was therefore studied in which a wedge-shaped section was removed from the ventral wall of the bronchus to the left diaphragmatic lobe. This section included half the circumference of the wall and measured up to 1 centimeter in width at the point of maximal separation (see insert in Fig. 2). Three such control dogs died promptly of tension pneumothorax despite intensive aspiration as in the previous controls.

In 10 dogs the defect was patched with gelatin sponge precisely as in the previous

series and 9 of these survived without complication. In 1 dog considerable difficulty was experienced in maintaining the gelatin sponge in place but no fixation was used except the inherent adhesiveness of the material. As anticipated a small leak developed at the edge of the material and death occurred after 3 days from an infected pneumothorax. It is again emphasized that in all these experiments no sutures were employed to fix the gelatin sponge in place.

The microscopic appearance resembled that in the previous series save that the defects were larger. Figure 5 shows a defect 2 weeks after operation with the mucosa completely but irregularly regenerated. Under the microscope cilia may be seen on the epithelium which is heaped up markedly in some areas. The gelatin sponge is being actively invaded

Fig. 3 Bronchus encased in airtight seal of gelatin sponge. Insert shows how the pulmonary artery holds the overlapped sponge in position over the defect.

by fibrous tissue and over its surface beneath the bronchial epithellum there is a well organized lamella of loose fibrous tissue.

4 Lobectomy Fifteen dogs were subjected to removal of the left apical lobe, the bronchial stump being covered by a gelatin sponge. Details of the procedure may be seen in Figures 6 and 8. Because of the incomplete fissure between apical and cardiac lobes, a segmental type of resection was usually necessary. After ligation of the vessels and division of the pulmonary tissue the bronchus was severed cleanly without the use of clamps. The open stump was covered by a strip of gelatin sponge

slipped down on either side of the bronchus so that adjoining structures would prevent its displacement (Fig. 8).

Thirteen dogs tolerated the lobectomy well. Nine of these were killed from 3 days to 17 weeks after operation in order to study the healing process. Four are alive and well from 3 to 4 months after operation. Two animals died of empyema on the third and seventh postoperative days. In the first of these an attempt was made to cover the open bronchus by simply laying the gelatin sponge in place on the opening. The rapidly fatal course due to leakage around the gelatin sponge showed this technique to be unsuitable and it was not tried again. The second death occurred after removal of the upper and middle lobes on the left, leaving insufficient surrounding tissue to keep the sponge in position. Two controls in which no seal was placed over the bronchial stump died promptly after operation as soon as continuous aspiration of the pleural space was discontinued.

The manner of bronchial healing after closure by various methods has been discussed at length by Rienhoff, Gannon and Sherman. Bronchi closed by gelatin sponge would be expected to heal in much the same manner as those in which the pleura was simply drawn over the end of the bronchus. In the series of Rienhoff and his co-workers, the main bronchi were under treatment whereas in the present experiments only the bronchus to the left

Fig. 6 Bronchus to left apical lobe isolated after division of pulmonary artery and vein and separation of parenchymal connection with cardiac lobe

upper lobe was considered. However the general principles involved are the same.

Figure 9a is a photomicrograph of the cut bronchus to the left apical lobe sealed with gelatin sponge 3 days before the animal was killed under anesthesia. The gelatin sponge with red blood cells and serum in its meshes is seen to be closely applied to the cut bronchial cartilages. Extending up into the lumen of the bronchus is a loosely organized clot along one edge of which the bronchial epithelium is already beginning to proliferate (Fig. 9b). In another animal 6 weeks after lobectomy the end of the bronchus is seen to be well covered by ciliated columnar epithelium and the gelatin sponge has been replaced by loose fibrous tissue so that no trace of its original structure remains (Fig. 10a and b).

RESISTANCE TO INTRABRONCHIAL PRESSURE POST MORTEM

From the photomicrographs one would infer that the healed bronchi would withstand a considerable pressure of air without leakage. This inference is substantiated by the results of inflation studies of the lungs *in situ* immediately after death. The lungs were inflated under water to a maximum pressure of 80 millimeters of mercury beyond which point leakage generally occurred around the inflated balloon on the endotracheal catheter. Usually the parenchyma of the lung began to leak before this pressure was reached. The pressures

Fig. 7 Left apical lobe drawn medially in order to allow insertion of gelatin sponge between bronchus and pulmonary artery

attained and the results in the various categories are shown in Table I.

In only 1 instance was a leak found at the site of a gelatin sponge patch; this occurred in a bronchus partially sectioned a week previously. The repaired area in this animal transmitted air after the pressure reached 25 millimeters of mercury. In a second animal treated similarly and tested after 1 week the repaired area resisted a pressure of 80 millimeters of mercury. There was considerable variation in the pressure at which the lung parenchyma leaked; in many cases there was no leak at 80 millimeters of mercury whereas one lung from which adhesions had been separated in opening the chest at autopsy leaked at a pressure of 20 millimeters of mercury. As is well known a pressure of only 8 to 10 millimeters of mer-

curry is required for full expansion of the lung in the dog

DISCUSSION

It is apparent that in the dog bronchial openings produced in a variety of ways may be healed successfully by the use of gelatin sponge without suture fixation. In 10 partial sections of the bronchus to the left diaphragmatic lobe all animals survived when a patch of gelatin sponge was used. As a more severe test of the method it was employed after removing a segment of the ventral wall of the bronchus to the left diaphragmatic lobe in 10 animals. All but one of these healed satisfactorily. Fifteen dogs

were subjected to removal of the left apical lobe, with gelatin sponge as the only covering for the bronchial stump. Thirteen of these survived. The 3 deaths in the two latter groups occurred as a result of infection, presumably originating in the open bronchus.

Microscopic study of the operative areas showed organized fibrous tissue well covered by epithelium. In bronchi not deformed by suture of the cut edges the tissues seemed to achieve a smooth, firm union fairly rapidly.

In the course of segmental or total lobectomy in man, one occasionally encounters a partial severance of an adjoining bronchus. The repair of such accidental bronchial lesions presents a difficult problem particularly when a wedge of bronchial wall has been removed. Suture of such a lesion may deform the bronchus and lead to atelectasis and suppuration

Fig. 10 a, left, Six weeks after lobectomy the end of the bronchus is firmly sealed and there is no trace of the gelatin sponge. $\times 6$ b Higher magnification of Figure 10a. Normal epithelium is seen covering the end of the bronchus. The underlying connective tissue is very loose. $\times 69$

distal to the area of repair. It seemed that a patch of absorbable material placed over such a lesion would be more conducive to healing without deformity than any other method. Such a clinical possibility prompted the studies detailed here. Results were fairly successful even though the gelatin sponge was not sewed in position. With suture fixation it seems likely that better results could be achieved and the safety of the method could be increased to a point at which clinical trial might become advisable.

The present studies demonstrate merely the validity of the concept that an absorbable material may be used for closure of experimentally produced openings in the bronchi. However, it must be stated emphatically that the particular technique described here is not recommended for clinical use. This technique purposely omitted factors which might have been expected to enhance its safety in order to provide a more rigorous test. Moreover, the results in animals, even if perfect, cannot be used except as an indication of possible clinical applicability. As Bailey(1) has aptly stated

it must be recognized that closure of the bronchus in animals is only slightly comparable to the problem as met in clinical human cases. A momentary consideration of the smallness of the bronchi in animals, the absence of previous bronchial or pulmonary infection, the absence of previous pleural adhe-

sions, and the great mobility and redundancy of the mediastinum will indicate the contrast. The studies of Rienhoff and others on closure of the bronchial stump by mere approximation of the pleura over it lend further support to this view.

There are currently a number of accepted methods for bronchial closure. Most of these recognize certain principles in bronchial healing among which are the preservation of the blood supply by avoidance of crushing clamps or constricting ligatures and the pleuralization of the occluded bronchial stump. Sweet has reported 140 instances of bronchial closure with only 1 known failure. It would certainly be rash at present to suggest the clinical use of the method as described here when results under relatively ideal experimental conditions are not as satisfactory as those of Sweet just noted.

However, the danger of deformity or stenosis following the usual type of repair in accidental bronchial wounds suggests that a modification of the present gelatin sponge method may be helpful in such accidents. Its use in conjunction with standard methods of bronchial closure after pulmonary resection must also be considered. Moreover, with increasingly radical removal of neoplasms involving the carina or lower trachea, the need for a satisfactory technique of repairing such defects is apparent. The ingenious work of

Daniel in this connection is a striking example of one approach to the problem. He replaced entire segments of the tracheobronchial tree in dogs with glass tubes and removed the tubes bronchoscopically many months later at which time tracheobronchial continuity had been restored. The use of absorbable materials in a similar connection is an attractive possibility that is now under investigation in this laboratory.

SUMMARY

Absorbable gelatin sponge has been used as a seal for various experimentally produced bronchial defects in dogs.

In 10 dogs a transverse partial section of the bronchus to the left diaphragmatic lobe was sealed by gelatin sponge with uniformly good results.

In 10 dogs a segment was removed from the ventral wall of the bronchus to the left diaphragmatic lobe the defect being covered with gelatin sponge. All but 1 of these dogs recovered.

In 15 dogs the apical lobe of the left lung was removed the bronchial stump being cov-

ered with gelatin sponge. Thirteen of these recovered.

In no instance were sutures used to hold the gelatin sponge in position reliance being placed solely on the retaining effect of adjoining structures plus the adhesive qualities of the material when moistened with body fluids. By the use of suture fixation one would expect increased reliability of the technique.

Although the present technique is not advised for use in patients, the general principle of sealing bronchial defects by absorbable material may have clinical applicability.

DISCREPANCIES IN MYELOGRAPHY

Statistical Survey of 200 Operative Cases Undergoing Pantopaque Myelography

WILLIAM BEECHER SCOVILLE, M.D., Hartford Connecticut, WILLIAM HENRY MORETZ,
M.D. Salt Lake City Utah and WALTER DOUGLAS HANKINS M.D.,
Johnson City Tennessee

MANY excellent articles have extolled the virtues of pantopaque and other contrast myelography in the study of the ruptured intervertebral disk (4 5 6 7 13). This article attempts to point out certain limitations of this diagnostic method and represents a survey of 200 operative cases from Cushing General Hospital in 1944-1945.¹ In the discussion 2 additional unpublished surveys will be included for the sake of comparison. The survey was undertaken when the neurosurgical author (W.B.S.) and several independent roentgenologists (author W.D.H. Danelius and Ogden) commented on the difficulty in making a clear cut diagnosis of the presence or absence of a ruptured disk by myelography alone. It was our collective impression that myelography yields equivocal findings in at least 25 per cent of the cases. If true this was at variance with published statistics.

LITERATURE

Statistical surveys of which there have been many (4 6 8 13) give an overall accuracy of 92 to 93 per cent in contrast myelography regardless of the media used. When analyzed such statistics are erroneous as they are based on positive myelograms only; those cases of normal myelograms which nevertheless reveal a ruptured disk at operation being ignored. This was commented upon by Pugh. Only recently have surveys (1 2 15 16) suggested a higher percentage of error and only Maltby and Pendergrass have devoted an entire and excellent article to the diagnostic errors found in myelography. However no

corrected statistics have been published yet to supplant the older euphemistic reports.

The causes for error have been well described (12) and include (1) double disks which occur in 12 to 14 per cent (4 16);² (2) a high cul-de-sac (1 6 14 16); (3) a giant canal; (4) a congenitally narrow dural sac; (5) post-operative defects and adhesions; (6) so called subclinical protrusions or hidden disks of Dandy consisting of a torn annulus with fragmentation and degeneration of the nucleus pulposus and occasionally cartilaginous plate but without actual protrusion. Too much stress has been laid on thickened ligamenta flava and varices and too little on that most common cause of error a lumbosacral "disk" situated so far laterally as to give no dural or root sheath defect at all (1). Disagreement exists on the diagnostic importance of asymmetry of root sheaths. Horwitz gives us all food for thought in his study of 100 autopsied spines in which he found that asymptomatic multiple protrusions with actual degeneration of the nucleus pulposus are a common occurrence throughout the adult spine.

SURVEY

Two hundred consecutive cases in which patients were subjected to pantopaque myelography and operation for a lumbar ruptured intervertebral disk were studied at the Cushing General Hospital. That technique now generally accepted throughout the United States was used for pantopaque myelography (11 17). Spot films were taken in both postero-anterior and oblique views in all cases. Lateral views were omitted because of technical

difficulties and lack of agreement as to their advantage over oblique views (3-9). Operation was carried out because of clinical evidence of a ruptured disk plus a considerable physical disability. In this series more patients with mild symptoms underwent operation than would have been operated upon in civilian life because of that universal G. I. tendency to turn in at the first hint of disability. All myelograms were reviewed jointly by the roentgenologist and neurosurgeon without knowledge of the clinical or operative findings. Comparison was then made between the myelographic diagnosis and the operative findings.

A positive finding at operation was defined as (a) a frank herniation of degenerated nuc-

lear fragments through a torn annulus or (b) a marked 'bulge' of the annulus, with softening and a true 'stringy' degeneration and fragmentation of the nucleus and at times fragmentation of the cartilaginous plate. The so-called 'hidden disk' of Dandy was excluded as were tumors simulating ruptured disks.

Errors in diagnosis were divided into *major* and *minor*. Major errors constituted those in which the myelographic diagnosis was in direct contradiction to the operative findings, i.e. a myelogram incorrectly diagnosed as normal or as abnormal. Minor errors included (a) errors in localization either by interspace or lateralization, (b) errors in differentiation between single and double disks, and (c) errors of technique.

25 or 13 per cent *false negative* and 7 or 4 per cent *false positive* cases. All but one of the false negatives yielded disks in the lumbosacral interspace at operation.

5 *Minor errors* occurred in 33 or 17 per cent of 196 cases. They consisted of 6 or 3 per cent, errors in *technique* and 27 or 14 per cent errors in *localization*. Errors in localization were further subdivided: 6 per cent were due to mistakes in the localization of a single disk; 5 per cent were due to double myelographic defects with a single disk found at operation; and 3 per cent were due to a single myelographic defect with double disks found at operation.

DISCUSSION

In order to rule out the personal equation from these diagnostic errors a comparison was made with an independent survey carried out under identical conditions in 1945 to 1946 by Drs. Gerhard Danelius and Frank Turney, respective chiefs of the roentgenological and neurosurgical services at McCaw General Hos-

pital. They have kindly permitted their results to be quoted in this article and it is to be hoped that their painstaking survey will be published as a separate article. Their results were roughly comparable with the exception that their major errors were less than one-half of ours. Overall errors were 24.4 per cent; major errors were 7 per cent; minor errors were 21 per cent including 9 per cent of technical errors.

For further comparison a small survey of 25 consecutive civilian cases was carried out at the Hartford Hospital in 1946 by Dr. Ralph Ogden, roentgenologist and the author (W.B.S.). More rigorous preoperative clinical criteria as well as operative criteria were used with the result that only one negative exploration was performed and operative findings revealed the presence of actual herniation of disk fragments through the annulus fibrosus in every other case. In spite of these criteria and the benefit accruing to the author from his experience gleaned in the other series the results were again comparable to the original survey.

Overall errors were 28 per cent major errors were 12 per cent minor errors were 15 per cent There were no technical errors. Double disks occurred in 1 case or 4 per cent

Our high percentage of error in myelographic diagnosis as compared to previous reports is apparent rather than actual. If our statistics shall be limited as they are in the older articles to only false positives (i.e. those myelograms incorrectly indicating the presence of a disk not found at operation) and to technical errors the percentage of discrepancies in our survey will be exactly comparable to those previously reported namely 7 per cent or an accuracy of 93 per cent

From a detailed analysis of our survey it appears that the largest percentage of error occurs in those myelograms incorrectly diagnosed as normal. In fact if operation shall be performed upon all cases having clinical evidence of a disk but a normal myelogram an error in myelography will be found in 74 per cent of those cases. Twenty four of 25 cases in thus 74 per cent will reveal a laterally placed lumbosacral disk at operation. The second largest percentage of error occurs in the false localization of single disks. These 2 groups together cause 50 per cent of all myelographic errors. In contradistinction technical errors are few and the positive myelograms will be correct in 95 per cent of the cases

With the above in mind these writers will continue to use pantopaque myelography routinely on all ruptured disk suspects but will tend to discount all normal myelograms if contradicted by the clinical findings.

CONCLUSIONS

1 Clinical evidence of a ruptured disk is more important than is myelographic evidence.

2 A positive myelogram is more important than a negative myelogram. A negative or normal myelogram in the face of clinical evidence of a ruptured disk will be wrong three out of four times

3 Myelography fails to rule out the presence of a laterally placed lumbosacral disk. In 24 of 25 cases of ruptured disk in which the

myelograms are normal, the location is in the lateral lumbosacral interspace.

4. Root sheath asymmetry is an important yet equivocal myelographic sign which may or may not indicate the presence of a ruptured disk. It is of little value without confirmatory clinical evidence.

5 Myelographic double defects are more common than are actual double disk ruptures or herniations.

6 When myelography is used as the sole diagnostic criterion the overall error is in the neighborhood of 25 to 35 per cent in contrast to the 6 to 8 per cent cited in the literature.

WOUND HEALING IN EARLY AMBULATION

HENRY P ROYSTER M D LILLIAN I McCAIN B A., and
ALEXANDER SLOAN B A Philadelphia, Pennsylvania

THE recent work of Leithauser (3) has refocused attention in this country on the advantages of early postoperative ambulation. This method of treatment has often been a source of doubt in the minds of surgeons who naturally might fear a disturbance in wound healing especially after laparotomy. The possibility of rupture of the abdominal wound or subsequent herniation has long been a hindrance toward getting patients out of bed soon after operation despite reports (5) which specify that in case of wound rupture the majority of these accidents occur before the patient becomes ambulatory.

This work was designed to compare the tensile strength of abdominal wounds of a group of dogs exercised daily after operation with a similar group closely confined. The conditions reproduced as nearly as possible those of patients treated postoperatively by bed rest and by early ambulation.

METHOD

In healthy well fed dogs weighing between 6.5 and 14.0 kilograms right rectus muscle splitting incisions into the abdominal cavity were made under aseptic precautions. The incisions which averaged 8.0 centimeters in length, were placed midway between the xiphoid and the symphysis and were sufficiently long to yield enough material at suture line for duplicate determinations of tensile strength and for microscopic study. Transverse upper rectus incisions were made in 2 dogs.

After difficulty in obtaining wounds completely free of infection in the beginning of the experiment the abdomens of all animals were clipped on the day prior to operation and washed with a detergent. This preoperative preparation reduced stitch hole abscesses to

infrequent occurrences. On day of operation the abdomens were shaved scrubbed with soap and water and then painted with iodine and alcohol.

The incision was carried down through the peritoneum and staggered in the several layers so that the lines of incision were not superimposed. The wounds were handled gently without the aid of retractors and clamps were applied only for suture of the peritoneum posterior rectus layer. Suture material consisted of No. 0000 silk except for a few animals in which part of the sutures were No. 000 plain catgut. Continuous sutures of silk were used in the peritoneum posterior rectus fascia anterior rectus fascia, and subcutaneous tissue. A continuous subcuticular suture was used for skin closure, with an occasional interrupted external skin suture for perfect coaptation. Collodion was the only external dressing in most of the animals. External sutures were removed by fourth to sixth day. After preparation of segments of tissue for the tensiometer the silk was extracted from the suture line.

On the day of operation the animals were weighed and blood serum protein levels were determined by the copper sulfate method (7). At the time of sacrifice all dogs with the exception of a few, were again weighed and the serum protein levels determined.

Maintenance of protein and caloric intake was kept very high but metabolic studies were not done. All animals were given and observed to eat a dietary of bread, fresh milk, beef and commercially prepared dog food.

Twenty six animals were operated upon and used for the experiments. The wounds of all were free of infection although small isolated hematomas were present in six. The protocols of these animals were included since the tissue to be tested was separated by several centimeters of normal tissue and the tensile strength was not considered to be affected. After operation 2 groups of 13 each were

Fig. 1. Die fitted with razor blades to cut centimeter wide segment of skin (Zantel's method personal communication)

formed. The animals of one group, the control, were confined to metabolism cages, the small dimensions of which afforded little opportunity for movement (2 by 3 feet). Those of the other group, the experimental one, were not only allowed free movement in a large pen but were also exercised at regular intervals including the day of sacrifice. The exercise begun on first postoperative day was given in 20 minute periods twice daily. During each exercise period animals were raced up and down several flights of steps and then taken

Fig. 2. Segments of anterior abdominal wall skin of dog, cut with die completed to show contraction. A "scoring" of skin as a preliminary step before the deeper cut is made. Anterior rectus fascia and peritoneum-posterior rectus layer were treated in like manner. Eight days postoperative.

out of doors for a run. Each dog was also danced around on his hind legs several times.

The animals of both groups were killed by intracardiac ether injection with the day of sacrifice taking place at intervals of 4, 6, 8, 10, and 14 days after laparotomy. A few were killed on the thirteenth and sixteenth days. Two transverse segments each of skin, anterior rectus fascia and peritoneum-posterior rectus fascia, were excised so as to include the vertically placed suture line in the center of the strip (Figs. 1 and 2). The tensile strength was then determined on the tensiometer as described by Meade from a modification of the technique of Howes, Sooy, and Harvey (Fig. 3). The two readings on each layer of tissue were averaged and a single value obtained. Sections of each layer were removed for microscopic study.

The unit of measurement of the tensiometer is grams, and since all tissues were cut so that the width at the suture line was 1.0 centimeter, the tensile strength of the tissues is then recorded as grams per centimeter. A small error in cutting the tissue so that it becomes wider or narrower than the standard may mean a large difference in tensile strength. Care was taken to remove the segments of tissue after

Fig. 4. Postoperative weight changes in ambulated and control animals.

Fig. 5. Postoperative serum protein changes in ambulated and control animals.

death in the intact animal under normal skin tension

GENERAL CONDITION OF ANIMALS

In the experimental group the animals were reluctant to walk during their first period of exercising. It was only with difficulty that

they could be kept moving for the full 20 minutes. By the time of the second exercise period on the first postoperative day the animals were anxious to be put on the leash and their physical strength appeared to be increased. The animals of the control group remaining in cages were otherwise given the

Fig 6 Determination of tensile strength of skin wounds in ambulated and control animals

same individual attention. The difference in the amount of exercise amounted to more than that of the two daily exercise periods since the ambulated group moved freely around their large room while those in cages were disinclined to move except at times of feeding and cleaning out of their quarters.

The advantages of early postoperative ambulation which have been described in man in numerous reports (4) have their counterpart in the dog. In every instance the animals of the ambulated group in contrast to those in confinement, were more lively and kept their coats in cleaner condition. Smoother function of the gastrointestinal tract was indicated by heartier appetites and more regular and thorough defecation. Often the control dogs would be constipated for a few days but this was never noted in the ambulated group.

CONDITION OF THE WOUNDS

Gross examination of the wounds disclosed no differences between the two groups. The incisions appeared the same as in other healthy animals not subjected to the conditions of this experiment. There were no wound ruptures or evidences of gross infection. Three small hematomas occurred in each group but since

these were well localized and isolated it was considered that the tensile strength of these wounds was not affected. The hematomas occurred in wounds in which hemostasis was difficult to accomplish; their presence was due to errors in operative technique rather than to the effect of early postoperative ambulation.

The weights of 19 animals on the day of operation and on the day of sacrifice were recorded (Fig 4). Nine of these animals were in the control group and of these 9 only 3 animals showed a gain in weight over the course of the experiment. At one extreme one animal sacrificed on the sixth day gained 10 per cent over his preoperative level and at the other a loss of 19 per cent was observed on the fourteenth day. In contrast of the 10 animals in the ambulated group with data on weight, only 2 lost weight. One of these dogs developed diarrhea from overeating fresh meat.

In 23 animals blood serum protein levels were determined on the day of operation and at sacrifice (Fig 5). The preoperative values were at 5.4 grams per 100 cubic centimeters or above. Of 12 in the control group 2 were reduced below the preoperative level. Both of these animals lost weight. In the ambulated group the levels in 4 animals were low at the

Fig. 7. Determination of tensile strength of anterior rectus fascia wounds in ambulated and control animals.

Fig. 8. Determination of tensile strength of peritoneum-posterior rectus fascia wounds in ambulated and control animals.

time of sacrifice, and of these only 2 also lost weight.

TENSILE STRENGTH

The tensile strength determinations were plotted so that similar tissues could be com-

pared in the two groups. The mean curves in Figures 6, and 8 show that the strength of the wounds in the ambulated group closely matches that in the control group. The approximate coincidence of curves is true of skin

Fig. 9. Dog 235. Healing wound of anterior rectus sheath. Early ambulation. Fourth postoperative day showing profuse growth of fibroblasts across wound gap. F and F indicate cut edges of fascia. $\times 45$.

anterior rectus fascia, and peritoneum posterior rectus fascia. In fact, not only the curves but also the actual values are nearly identical with those in the original report in 1929 by Howes, Sooy and Harvey. Consequently the strength of the three important layers of the abdominal wall is neither increased nor weakened by early postoperative exercise.

HISTOLOGY

On histological examination no differences could be found between the control and ambulated groups of animals. The process of fibroplasia was well advanced by the fourth postoperative day and fibroblasts were abundant throughout the several layers of tissues. By the fourteenth day the scars were well organized and vascularized (Fig. 9).

DISCUSSION

Since epithelization is of minor significance in aseptically incised and primarily sutured wounds Howes, Sooy and Harvey have shown that the single factor of repair by fibrous tissue can be measured accurately enough for analysis by determining the tensile strength at intervals after operation. Any change in healing of the cleanly sutured abdominal wound must then be demonstrated by an effect on the latent or lag period, the phase of fibroplasia or maturation. The strength of the wounds in this experiment on the fourth postoperative day is sufficiently great to eliminate early ambulation as a cause of prolonging the latent

period. The period of fibroplasia is characterized by an abrupt rise in strength of a sort consistent with the 'normal' curve of wound healing by this method. Study of the phase of maturation was incomplete since our interest lay in the condition of the wounds in the early days after primary closure during the time when wound rupture is most common. Kimbarovskiy in 1940 performed an experiment on dogs in which he found that the wounds of animals placed in casts showed delay in connective tissue formation when compared with others that were ambulatory. Newburger reported increased strength of abdominal wounds in rats exercised daily on a treadmill. The results obtained by these investigators cannot be accurately correlated with the present work due to the wide difference in experimental conditions.

SUMMARY AND CONCLUSIONS

1. Studies of serum protein, weight change and tensile strength of the abdominal wound were performed in 26 dogs.

2. One half of the animals were kept inactive after operation and the others were treated by early postoperative ambulation.

3. Comparison of the two groups is as follows:

a. The general condition of the ambulated animals was improved over that of the controls.

b. A significant number of animals in the ambulated group gained weight while the controls generally lost weight.

c. The tensile strength of the postoperative abdominal wound in the ambulated group did not differ significantly from the values in the control group.

DIFFERENTIAL SPINAL BLOCK

IV The Investigation of Intestinal Dyskinesia, Colonic Atony, and Visceral Afferent Fibers

STANLEY J SARNOFF M.D., JULIA G ARROWOOD M.D., and WILLIAM P CHAPMAN M.D.
Boston Massachusetts

THE occurrence of disordered motor states of the intestine as a puzzling incapacitating and occasionally fatal syndrome has long been recognized. Murphy in 1896 reported spasm of the bowel simulating acute mechanical intestinal obstruction in a painter. This report was followed by 3 cases of spastic ileus from Heidenhain's Clinic in 1897 and by 1910 protocols were available on 51 cases in which spasm was sufficiently pronounced to cause obstructive symptoms in the absence of organic mechanical interference with the lumen (16a). Engstad in 1928 reported 6 cases of spastic ileus of the jejunum verified by operation. Zimmerman in 1930 added 2 cases of his own to the 157 available cases in which spasm of the bowel was thought to be the cause of obstruction. The following year Christianson and Borgen published 5 cases that had abdominal distention, cramps and vomiting for which no mechanical cause could be found. Steigmann and Singer published the protocol of one case of idiopathic neurogenic spastic ileus which terminated fatally and cited 14 similar fatal cases. Colp in 1941, reviewed the literature on spasm of the colon as a cause of intestinal obstruction and published protocols of 5 cases of his own. White and Smithwick published the report of a most interesting patient with intermittent periods of vomiting, severe constipation, increased peristalsis and pain coming in waves. Four laparotomies had not been of help. Paravertebral procaine injections conferred relief and the ensuing sympathectomy was successful. Chesterman in 1946 elaborated on the Alvarez theory of intestinal

gradients to explain the cases of neurogenic ileus that had come to his attention. The articles mentioned and their appended bibliographies comprise the available literature on the clinical aspects of spastic ileus.

It is admittedly difficult to evaluate some of the reviewed cases in terms of whether or not actual spasm was the sole cause of the patient's disease. Nevertheless enough well authenticated and directly observed material is available to ensure the importance of deranged intestinal motor function as a surgical syndrome. And yet, only rarely is it considered as a part of the differential diagnosis when crampy abdominal pain, persistent obstipation, abdominal distention and tympanites are encountered.

One of the underlying reasons for this is the fact that it is frequently difficult or impossible to make the diagnosis of neurogenic intestinal obstruction preoperatively. When a patient recovers from a bout of obstruction either spontaneously or with the help of intestinal intubation, the intestine is said to have unlinked or the edema subsided, allowing reestablishment of intestinal transport.

The use of a sympathetic block to alter bowel motility and transport was first suggested by Wagner in 1919. Eight cases of abdominal distention responded well to splanchnic anesthesia with procaine. Since then splanchnic or spinal anesthesia has been used many times in intestinal distention of varying sorts and with varying success (7). The laboratory experiments of Domenech, David and Loring, Markowitz and Campbell and Ochsenrider, Gage and Cutting have put on a firm physiologic basis the value of interrupting the sympathetics in relieving the paralytic ileus induced by chemical or bacterial peritonitis.

From the Department of Surgery and the Anesthesia Laboratory of the Harvard Medical School, and the Surgical Services at the Massachusetts General Hospital.

The latter authors justifiably wondered why spinal anesthesia did not yield equally consistent results in the human. This point we believe has been resolved by the significant work of Helm and Ingelfinger (12-13). These investigators have convincingly demonstrated that morphine and atropine, presumably by a direct effect on the bowel, can prevent the increase in intestinal motility induced by spinal anesthesia. It is likely that an appreciable proportion of patients who have received spinal anesthesia for paralytic ileus were under the influence of either or both of these drugs. The importance of withholding medication when attempting to use spinal anesthesia to increase bowel motility and transport cannot be overemphasized.

For the most part spinal anesthesia has been used in *paralytic* ileus and has been used as a therapeutic measure. The classical clinical observations of Scott and Morton and of Smithwick (28) constitute the only attempts, of which we are aware to use it as a prognostic index in disordered motor states of the intestine. These workers concluded that if a spinal anesthesia, properly administered, induced motility and transport in an otherwise dilated and nontransporting colon, resection of the appropriate sympathetic fibers should cause clinical improvement. Smithwick also used a paravertebral block for the same purpose (28).

This report concerns itself with observations concerning the effect of blocking sympathetic visceromotor fibers on bowel activity and transport. It indicates the usefulness of a particular type of sympathetic block, differential spinal block (18-19, 20, 21) as a therapeutic measure in non-mechanical obstructions. Perhaps of more significance than the above are the data which indicate the usefulness of sympathetic blocking procedures in differentiating intestinal dyskinesia with a neurogenic component from the common type of acute mechanical intestinal obstruction.

MATERIAL AND METHOD

All patients were from the surgical services of the Massachusetts General Hospital. Five patients were given a differential spinal block in an attempt to alter temporarily bowel func-

tion. Two additional patients had the visceral afferent pathways (carrying the sensation of distention) tested while under the influence of a high differential block.

The technique of administering a differential spinal block has been previously described (18-19, 20, 21). Briefly it consists of the subarachnoid administration of a large volume of a dilute solution of procaine hydrochloride (0.5%). This is delivered from an elevated leveling bulb through a calibrated drip chamber to an infusing needle in the third lumbar interspace. The optimal initial dose is 16 cubic centimeters administered in about 4 minutes. The drip is then continued at the rate of 16 drops per minute until the desired block is accomplished. The drip is subsequently set at that rate which will maintain the block until it is no longer required.

The use of this technique has made it possible to produce a sympathetic block and a block of the fibers concerned with pinprick sensation without grossly affecting touch, position sense, vibratory sense, or motor power. The effect of this type of block on visceromotor function has not previously been investigated.

The distention stimulation of the jejunum and rectum was kept within constant limits by elevating the pressure within the intestinal balloon in a constant fashion. The balloon pressure was elevated to a given level by a given volume of air delivered in a given time.

The four balloon intestinal tube was constructed so that each balloon was placed 10 inches from its neighbor and led to recording pens via separate tubes. In this way a peristaltic wave starting in terminal ileum could be traced around to descending colon by the impression it made on each of the four balloons it passed (Fig. 1a). This apparatus will be described in detail in a separate communication (1).

PROTOCOLS

CASE 1: The first patient was a 38 year old married housewife, who was first seen in this hospital in 1933. Ten years previously an appendectomy had been performed following repeated attacks of right lower quadrant pain. The postoperative diagnosis was congenital adhesions. In 1940 the patient was said to have had acute intestinal obstruction and a lysis of adhesions was performed.

In July of 1933 while 6 1/2 months pregnant the patient was admitted to this hospital for the first time with cramp-like abdominal pain, nausea, and vomiting. This pain subsided spontaneously but recurred one week later and was accompanied by fecal vomiting and abdominal distention. A lysis of adhesions was performed under ether anesthesia but severe distention persisted for a week, and an ileostomy had to be performed at the end of that time. This relieved the patient completely and recovery was prompt. At the first operation it was thought that the point of obstruction had been freed but at the time of the ileostomy 10 days later the small intestine was again seen to be severely distended.

In November 1934 a cholecystectomy was performed following 3 severe attacks of right upper quadrant pain. Gall stones were found at operation. Soon after discharge a mental depression set in, and in January 1936 the patient was readmitted for psychiatric attention.

The cramp-like abdominal pain, vomiting, and distention reappeared after increasing bouts of constipation in July 1935 and at this time a laparotomy was performed under ether anesthesia. There was not a single adhesion involving the small intestine at any point, and only one apparently innocuous adhesion along the course of the transverse colon. The cecum was found to be large and redundant and was therefore fixed to the anterior abdominal wall with chromic catgut. Amniotic fluid was inserted into the peritoneal cavity. Ten days after operation the patient had a similar attack of abdominal pain, vomiting, distention, and obstipation with evidence of greatly increased peristalsis. This occurred at a time just after freedom from mechanical obstruction had been verified by direct observation. A psychiatric consultation was requested.

In September 1936 a similar obstructive attack followed the swallowing of three pins and a needle. The former were recovered in the stools but the latter was not found. The following month it was again found necessary to hospitalize the patient because of abdominal pain, nausea, vomiting, and abdominal distention accompanied by high pitched peristalsis. X-ray examination at this time revealed a markedly dilated colon with some spasm in the ascending portion.

In 1940 a right sacroiliac fusion was performed for the relief of low back pain. Obstipation, cramp-like abdominal pain, and distention necessitated hospitalization again in March 1941 and a barium enema revealed colonic atony and a long redundant sigmoid. No evidence of organic obstruction was found. The attack subsided spontaneously.

From January to December of 1944 repeated attacks of pain, vomiting, distention, and obstipation required hospitalization. Gastric suction and sedation were required to help the patient through each attack. No operation was performed. These symptoms reappeared again in March, 1946 and the patient again entered the hospital. At this time barium was introduced into the duodenum through an in-

dwelling Rehfuss tube. From this region barium passed through the jejunum and proximal ileum at a normal rate outlining essentially normal small bowel. However, at approximately the region of the mid ileum there was a retardation of flow and films taken over a period of 6 1/2 hours showed only slow progression of the barium to the cecal region. At the end of this time, considerable barium remained in the terminal ileum, but no cause was demonstrated for its exceedingly slow progress. An exploratory laparotomy was performed and careful examination of the entire intestinal tract was made. A few minor adhesions were found in the region of the hepatic flexure and the old gall bladder bed, and the cecum was found to be fixed to the anterior abdominal wall. No point of obstruction could be found and the remainder of the intestinal serosa was smooth and glistening. It was felt at this time that the previous attacks of intestinal obstruction had been due to some type of autonomic imbalance.

In October 1946 readmission was again found necessary and this time due to the patient's refractoriness. Intestinal suction was impossible and the patient went home unrelieved. Three weeks later the patient was admitted in the midst of a characteristic attack of cramp-like abdominal pain, vomiting, distention, and obstipation. It was decided to institute a study of the autonomic control of this patient's intestinal tract. Accordingly a differential spinal block was administered.

When this was done there was vasodilation in the lower, but not the upper extremity and a loss of pinprick sensation to the eighth thoracic segment. Sweating ceased on the lower extremities. There was no loss of motor power, touch or position sense. Prior to the onset of the block, the abdominal girth was 29.5 inches, distention and resistance were considerable. Coincident with the onset of the sympathetic block, intestinal activity became more active (borborygmi) and large amounts of flatus were passed. Within 40 minutes the abdominal girth was reduced from 29.5 to 26.5 inches and the abdomen became strikingly softer and flatter. The patient, an unusually competent observer, was impressed and elated with the results. She continued to pass gas throughout that afternoon and evening at the end of which time the abdominal girth was 25.5 inches. The patient stated that she felt perfectly normal at that time and it was her opinion that that attack had been abruptly and completely terminated.

Inasmuch as the 13 years from 1933 to 1946 had been filled with major attacks requiring hospitalization and minor episodes which the patient weathered at home, it was thought advisable to attempt more definitive therapy in order to prevent the progress of the downhill course this patient had traveled in the recent 16 months. Accordingly a right transthoracic sympathectomy was performed in December 1946. Abdominal distention without nausea, pain or vomiting appeared in the 4th, 5th, 6th and 7th postoperative days. The nature of the distention postoperatively will be discussed later.

Fig. 12. Schematic presentation of how the four balloon intestinal tube works. Each balloon is connected to a separate recording pen by a channel isolated from the other balloons and pens. By correlating the balloons A, B, C and D with the records A, B, C and D it can be seen that the peristaltic wave has passed balloons D and C and is now at B and has not yet arrived at balloon A in the descending colon.

At the present writing 9 months after operation, the patient has not required hospitalization and has gained 11 pounds in weight. She is carrying a normal work load satisfactorily and has had but two episodes of abdominal distress. One of these was accompanied by mild distention; neither attack lasted longer than 12 hours. A more complete evaluation will be made at a later date.

CASE 2. The second patient was a 24 year old registered nurse who entered the hospital on December 26, 1945, with the chief complaint of increasingly severe abdominal pain. In 1944 an appendectomy had been performed for right lower quadrant pain, accompanied by nausea and vomiting. From then on she suffered from the severe, cramp-like abdominal pain that culminated in her present admission. This pain was accompanied by vomiting during her more recent attacks. Periods of repeated attacks were accompanied by obstipation lasting up

to 4 days. Distention, although frequently present, was not a prominent feature of the clinical picture. Rather the attacks of excruciating pain were accompanied by a rigid boardlike abdomen and unless one was acquainted with her previous history the diagnosis of a ruptured viscus suggested itself. Three exploratory laparotomies had been performed for lysis of adhesions, and at the last operation a resection of an adherent loop of bowel was performed. Although the patient left the hospital slightly more comfortable after each of these procedures, she was never free of pain and had frequent severe attacks while out of the hospital.

Röntgenographic examination of the intestinal tract during attacks revealed the presence of exceedingly swift peristaltic rushes starting in the upper jejunum and carrying to the area of terminal ileum. No distinct point of obstruction could be identified, however.

Full spinal anesthesia using 120 milligrams in 4 cubic centimeters of cerebrospinal fluid brought about complete and immediate abolition of the typical attack on three separate occasions. The boardlike abdomen naturally disappeared under the in-

After two moderate bouts of intestinal distention with abdominal pain that was completely left sided in location, left thoracolumbar sympathectomy was performed on November 2, 1947. Since that time the patient has had no further distention and has had no abdominal symptomatology.

fluence of the full spinal anesthesia since the somatic motor neurons were blocked.

Following the onset of a typical attack, a differential spinal block was administered. Shortly after the rise in skin temperature and fall in blood pressure, the abdominal pain began to diminish and within 10 minutes was completely gone (Fig. 1b). The loss of appreciation of pinprick sensation extended to the second thoracic segment but there was no loss of touch, vibratory sense, position sense, or motor power. Despite the absence of the loss of motor power the abdominal wall lost its rigidity coincident with the disappearance of the pain. The interpretation of this patient's disturbance of intestinal motility will be made below after it has been demonstrated that visceral afferent fibers are unaffected by the introduction of that concentration of procaine used in a differential spinal block.

Following a right sided lumbodorsal sympathectomy this patient has had one episode of mild abdominal discomfort. At this writing she is free of symptoms and is carrying a normal nursing work load satisfactorily.

CASE 3 The third patient is a 32 year old unmarried nurse and is perhaps the most complex and interesting patient in the group albeit the least satisfactory from a long range therapeutic point of view. She will be presented only briefly here in relation to the effect of two differential spinal blocks performed during two of her many bouts of intestinal obstruction.

An appendectomy had been performed in 1933, and three laparotomies for lysis of adhesions had been performed before she was first seen in this hospital in 1941. From then until March 1946 the patient was admitted nine times with the signs and symptoms of acute and chronic intestinal obstruction and had three further laparotomies for lysis of adhesions and various sidetracking procedures including a resection of densely adherent coils of small bowel.

When seen in March 1946 she was in the midst of one of her characteristic attacks of abdominal distention and tympanites, cramp-like abdominal pain, vomiting and obstipation of 3 days duration. For the ensuing 3 weeks she was maintained on the Miller Abbot tube, intravenous feedings and minimal oral intake. During that period she had had only one spontaneous bowel movement. Just prior to the administration of the differential spinal block her abdomen was markedly distended and resistant and high pitched peristalsis was present.

When the differential spinal block was performed she sustained a loss of the appreciation of pinprick to the seventh thoracic segment, but had no loss of motor power, position sense or touch. The appearance of the abdomen changed radically under the influence of the block. The circumference fell from 31 to 26 1/2 inches and the resistance was greatly diminished. In general, the abdomen became distinctly softer and flatter in a period of 30 minutes. This was accompanied by a small bowel movement

Fig. 1b. Case 3. The top portion shaded in black represents the amount of pain the patient was experiencing from none at all to excruciating. The next three brackets represent the skin temperature of the upper and lower extremities, as indicated, in degrees centigrade. The lowest bracket shows the blood pressure in millimeters of mercury and the rate at which the intraspinal drip was administered in drops per minute (20 drops per c.c.) after the initial dose of 12 c.c. of the 0.2 per cent solution of procaine hydrochloride.

and the passage of large amounts of flatus. The intestinal sounds, followed from the beginning of the procedure likewise suggested a significant increase in co-ordinated intestinal activity under the influence of the block. It was interesting to hear the sounds change from the high pitched 'ping' to a more normal pitch as the distention disappeared. By 24 hours after the block the patient had had five bowel movements and had passed a great deal of flatus the abdomen remaining soft and flat. At the end of 48 hours nothing more was being passed per rectum and abdominal distention was becoming apparent.

Fig. Case 5. Roentgenogram showing this patient's toxic, redundant colon, 8 hours after the insertion of barium.

The patient was seen on one subsequent occasion in the Emergency Ward with more or less the same picture. It was apparent, however, at that time that she was heavily under the influence of a narcotic to which she had become addicted during the course of her many illnesses. A differential spinal block was promptly administered but had only a slight effect in relieving the distention and in promoting the passage of flatus. The patient was transferred to the Psychiatric Ward for badly needed attention but signed out against advice 48 hours later when it became clear that medication was to be withheld.

Subsequent transthoracic sympathectomy was carried out at another institution by Dr. Smithwick who demonstrated regrowth of splanchnic fibers. She is currently free of abdominal distention and although abdominal pain is still mentioned she now complains mostly of joint pain.

CASE 4. The fourth patient was a 38 year old housewife who entered the Massachusetts General Hospital for the first time on October 15, 1946 with the chief complaint of abdominal pain, distention and obstipation. She had her first exploratory laparotomy performed in 1936, in an attempt to determine the cause of her sterility. At that time a fixation of the round ligaments, appendectomy and myomectomy were performed. In May, 1937 a right tubal pregnancy was removed and the uterus suspended. Moderate intraperitoneal hemorrhage was

noticed at the time. The patient gave birth to a normal female infant in May, 1938. A second ectopic pregnancy was removed in 1941, and in March, 1942 after a period of severe abdominal pain, a left oophorectomy and hysterectomy were performed. In November, 1942 the right ovary was removed after additional abdominal pain. In the immediate postoperative period there was evidence of urinary extravasation and the abdomen had to be reopened for a ureteral repair.

In December, 1944 she was hospitalized and studied because of attacks of distention and what was described as subacute small bowel obstruction. At that time the patient noted that anything but a light meal was followed by attacks of distention.

In the first week of September, 1946, 6 weeks prior to her first surgical admission to the Massachusetts General Hospital she began having severe, cramp-like lower abdominal pain and intermittent periods of abdominal distention. This usually followed the ingestion of food. Between the time of onset and admission she had lost 23 pounds, because of abstinence from food. She had moved her bowels only once in the 2 weeks prior to entry and the passage of gas gave her great discomfort.

The periods of distention were observed while she was in the hospital and a correlation between them and the ingestion of any sizable amount of food was established.

All who saw the patient agreed that her symptoms had to be evaluated against a highly neurotic background and this impression was confirmed by numerous bizarre symptoms such as radiation of the lower abdominal pain to the shoulder and down the leg.

A differential spinal block was performed on October 25, 1946 with the four balloon intersubcutaneous in place. It was determined at the time that the periods of severe pain were, in general, accompanied by peristaltic waves of increased height. This was helpful in establishing the genuine nature of the pain. Other than that, little of interest was obtained from the tracings. Following the block the patient began to pass flatus and continued to do so. The following morning the abdomen was observed to be scaphoid. It had not been flat since admission. The distention, pain and high pitched peristalsis remained absent for a day, and the patient felt that her intestinal tract was acting normally for the first time in 7 weeks. On the third day after the block the patient reverted to her former status.

Opinion as to whether to do an exploratory laparotomy or a sympathectomy was evenly divided at that time. Three factors spoke for sympathectomy: (a) the decided, albeit temporary, change in the clinical picture which followed the differential spinal block; (b) the recurrent nature of peritoneal adhesions with the tendency for the patient to enter "that dreadful downhill road on which the surgeon cuts the adhesions and the patient reforms them until either the surgeon tires or the patient dies";

Lord Moyalman.

Fig. 3. Case 5. The above tracings were obtained by means of a four balloon intestinal tube. Tracing A is from the balloon in the descending colon. Tracing B is from the balloon in transverse colon. Tracing C is from the balloon in ascending colon. Tracing D is from the balloon in terminal ileum.

The lower bracket represents the skin temperature of the lower extremities in degrees centigrade the range is from 28 to 33 degrees. Each vertical line represents a 5 minute period. The differential spinal block was begun 20 minutes prior to the beginning of tracing.

(c) the patient's life was in no immediate danger from the obstruction since it was intermittent and the vomiting was limited. Since the patient's symptoms were more pronounced on the left a left sided sym plectomy was performed on November 1, 1946.

The patient began to eat and have normal bowel movements on the second postoperative day. With the exception of one bout of distention on the tenth postoperative day the preoperative symptoms of distention, pain, high pitched peristalsis, and constipation with painful defecation were absent in the immediate postoperative period. A troublesome intercostal neuritis subsided only slowly but finally disappeared.

At this writing 11 months after operation it is difficult to be certain of what has been accomplished by symplectomy. The patient has had two episodes of right sided abdominal pain with a questionable distention. The background of a deeply rooted hypochondriasis makes the certain evaluation of her status impossible. However following the cessation of the medication that was necessary for the intercostal neuritis she began to gain weight and is now 11 pounds over her admission weight. Hospitalization has not been necessary, and she is carrying a normal work load satisfactorily.

CASE 5. This 45 year old housewife was admitted to the Massachusetts General Hospital on September 26, 1946 with the chief complaint of increasingly severe constipation. The past history revealed that she had been somewhat constipated since early childhood but 13 years ago at which time radium sterilization was carried out she noted that her symptoms had become much more severe. Four years ago after x ray examination a diagnosis of enlarged

atonic colon was made at another institution and diet therapy was instituted. She was told to stop taking enemas and cathartics, and during that period would go as long as 7 days without having a bowel movement before finally resorting to colonic irrigation.

The patient was seen to be a highly nervous easily upset individual who seemed to magnify minor difficulties into major obstacles. X ray examination revealed a redundant, atonic colon that did not empty for at least 8 hours after the insertion of the barium (Fig. 2).

During the course of the clinical evaluation of this patient a condition a differential spinal block was done with the four balloon intestinal tube in place.

As the block was pushed upward sweating ceased, vasodilatation occurred in the lower extremities and there was a loss of the appreciation of pinprick to the sixth thoracic segment. There was no loss of touch position sense vibratory sense or motor power. It can be seen that as the vasodilatation became maximal in the lower extremities the colon previously quiescent became extremely active. The height of the contractions was twice to three times that of any previous waves recorded in this patient. (Continuous recordings of 2 hours duration had previously been obtained.) This activity lasted until the subarachnoid drip was discontinued and the skin temperature began to fall. The sequence of contractions from ileum to ascending to transverse to descending colon leaves little doubt that this activity represents true peristalsis and not simply segmental or ring like contractions (Fig. 3).

That this burst of colonic activity was spontaneous or a mass peristaltic rush and simply coincident

Fig. 4. Case 6. The above figure presents the data obtained on skin temperatures in degrees centigrade. The time at which identical duodenal stimuli were applied are shown by the arrows, the plus marks indicating an undiminished response. The arterial pressure in millimeters of mercury is also shown. The differential spinal block was started at the first vertical line discontinued at the second. At 6:30 p.m. there was an abolition of vasoconstriction in the upper as well as the lower extremity, sudomotor block of the entire body, and loss of pinprick sensation to the angle of the jaw. At no time was there any change in the sensory threshold to balloon distention of the duodenum. There was no loss of touch, position sense, or motor power.

dental with the block rather than a result of it must be considered. However two facts militate against such a conclusion: (a) the period of peristaltic rushes was 15 minutes, which is longer than one would ordinarily expect it to be on the basis of available evidence; (b) the time sequence in which the various events took place make it quite improbable that the colonic activity was an independent phenomenon.

The patient was discharged from the hospital on a low roughage diet and has taken a distinct turn for the better, having more or less regular daily bowel movements at the present time. The periods of constipation that she has experienced since discharge have been related in a very clear manner to periods of either overwork, mental tension, or as has frequently been the case, both.

CASE 6. This 36 year old patient entered the hospital on January 25, 1946 for the evaluation of chronic, epigastric pain concerning which a diagnosis had not previously been made. In the course of the investigation a differential spinal block was performed with an infusing balloon in the fourth portion of the duodenum. Prior to the onset of the block the sensory threshold was determined in terms of the number of cubic centimeters of air that it was necessary to inject in a given time in order to elevate the balloon pressure to a given level. The differential spinal block was instituted and carried upward until there was a vasomotor and sudomotor block in the upper as well as the lower extremities and there was a loss of the appreciation of pinprick up to the angle of the jaw. There was no loss of touch, position sense, or motor power. Throughout the procedure repeated determinations of the sensory threshold to duodenal distention were carried out (Fig. 4). At no time was there any change in the threshold of the sensation of duodenal distention.

This case is presented in order to demonstrate the fact that the fibers carrying impulses which are concerned with the sensation of intestinal distention are not influenced by that concentration of procaine capable of blocking sympathetic efferent and proprioceptive fibers.

CASE 7. This 60 year old retired physician was admitted to the hospital for the study of intractable rectal pain of 20 years duration. During the preceding 20 year period numerous rectal and bowel operations had been performed including hemorrhoidectomy, excision of anorectal scar tissue, resection of sigmoid intussusception, and sigmoid colectomy. In the course of the investigation of the rectal pain a differential spinal block was performed. Block of vasomotor and sudomotor fibers was obtained in the upper as well as the lower extremities, and there was a loss of the appreciation of pinprick to the second thoracic segment. A balloon had been inserted 9 inches up into the rectum and at no time was there any diminution in the appreciation of rectal distention. There was no loss of position sense, touch, or motor power.

The results indicate that the fibers carrying the impulses concerned with the appreciation of intestinal distention are not blocked by that concentration of procaine which is capable of blocking sympathetic efferent fibers in the subarachnoid space.

Two other sets of data, not included here, confirm the above impression that visceral afferent fibers carrying impulses concerned with intestinal distention are relatively large heavily myelinated fibers.

RESULTS

The results may be summarized as follows

1 *Following the block of visceromotor fibers* to the intestinal tract by a differential spinal block definite evidence of increased propulsive and co-ordinated bowel activity was obtained in 3 patients Cases 1 3 and 5 In Case 5, this consisted of the increased height and frequency of contractions as determined by the 4 balloon intestinal tube. In Cases 1 and 3, the evidence consisted of a dramatic change in the appearance of the abdomen, and the passage of flatus and feces. In one of these patients, Case 3 a subsequent differential spinal block was ineffective while the patient was under the influence of a narcotic. Of the remaining patients studied for bowel activity the first, Case 2 had a disappearance of severe pain while under the influence of that concentration of procaine in her subarachnoid space which was incapable of interrupting the sensation of pain from distention Presumably therefore her relief was due to an alteration in or better co-ordination of bowel activity The last remaining patient Case 4 had no change in the activity of the intestine from which the intestinal balloon was recording but had a decided change in the appearance of her abdomen following the block.

2 *That visceral afferent fibers* (subserving the sensation of distention) are not blocked by that concentration of procaine hydrochloride capable of blocking sympathetic efferents, was demonstrated by Cases 6 and 7 Two additional patients, studied with the conventional type of spinal block, confirmed these data.

DISCUSSION

Previous investigations with differential spinal block (18 19 20 21) have been aimed in part at clarifying the morphology of the fiber size of the nerve roots in the subarachnoid space The evidence cited in the foregoing cases would indicate that visceromotor fibers are of about the same size and degree of myelination as other sympathetic efferents. This is in accord with Gaskell's early observations that preganglionic sympathetic efferents are all of about the same size (10) The visceral afferents on the other hand would seem to be larger more heavily myelinated fibers,

since impulses carried over them were not blocked by that concentration found to be capable of causing an efferent block It is interesting in this connection that Sheehan and Edgeworth demonstrated the presence of myelinated afferent fibers in the mesentery of the human This is of considerable interest in the study of the patients here presented since it suggests that the relief obtained from the differential spinal block was not due to the block of afferent impulses concerned with the sensation of distention The rational presumption would then be that it was rather due to the alteration of a disordered motor function, a correction of dyskinesia.

It is not the purpose of this report to present the merits of sympathectomy in this group of cases When the follow up period has been adequate a detailed report dealing with the whole symptom complex and etiology will be published by the gastrointestinal service of this clinic The above cases however indicate the ease with which intestinal dyskinesia can be confused with acute mechanical obstruction They likewise demonstrate the use of a sympathetic block in abolishing the obstructive attack and clearly demonstrate the participation of a neurogenic component

The diagnosis of neurogenic intestinal obstruction may be an exceedingly difficult one to make without the proof conferred by the results of some sort of sympathetic block. The chronicity of the complaint with a history of many minor as well as several major episodes is characteristic These patients were all diagnosed as being neurotic with varying degrees of hypochondriasis. All our patients but one were women and had undergone multiple laparotomies Under other conditions most of them would probably have had further abdominal exploration for lysis of adhesions One cannot help wondering whether some of the so called chronic adhesion formers who are subjected to multiple laparotomies would not benefit from an appraisal of the autonomic component Sometimes the 'point of obstruction' is not defined at laparotomy as precisely as might be desired and little is gained by the laparotomy other than the anesthesia to which the patient is subjected As often as not, this is spinal anesthesia

One may be called upon to use a differential spinal block in connection with this group of patients under two different sets of circumstances. The first is exemplified by Case 2 in which the visceral disorder was not life threatening and additional abdominal surgery was not considered at that time. The second type is exemplified by Case 1 in which the clinical picture was not sufficiently clear to rule out an acute organic mechanical obstruction. It would seem wisest under these circumstances to set the patient up for laparotomy with a continuous spinal needle in place and induce a full spinal anesthesia. A period of 60 to 90 minutes will suffice to bring about the passage of flatus and feces and a dramatic change in the appearance of the abdomen will occur if the obstruction has a significant neurogenic component. In retrospect the last laparotomy performed on the patient of Case 1 would almost certainly have been avoided if this course had been pursued.

It is important to omit the administration of morphine and atropine or scopolamine. For as Helm and Ingelfinger have pointed out these drugs inhibit the usual increase in bowel activity induced by spinal anesthesia, presumably by a direct effect on the bowel itself (12, 13). The fact that morphine can qualitatively alter the response of the bowel to a sympathetic block is of help in the interpretation of Case 3. At the time she was given the last differential spinal block the results of which were not impressive she was heavily under the influence of a narcotic although the exact drug was not determined. The patient was transferred from the Emergency Ward where the block was performed to the Psychiatric Ward where all medication was withheld and the intestinal distention gradually passed off.

It is interesting to speculate on the nature of the abdominal distention that occurred in Case 1 from the fourth to seventh postoperative days. It has long been known that in patients subjected to a preganglionic sympathectomy of the extremities for vasospastic disease, a period of autonomic activity occurs sometime in the first 10 days usually from the third to the seventh. This period carries with it a distinctly lowered skin temperature and

increased sweating of the denervated extremity. The nature of this postoperative postganglionic activity has recently been elucidated by Smithwick (25). Since the intestinal sympathectomy done in this patient was in part preganglionic it seems not unlikely that the observed intestinal quiescence from the fourth to the seventh postoperative days was due to activation of the decentralized postganglionic fibers just as is the vasospasm and sweating of the sympathectomized extremity. This intestinal phenomenon has been noted in patients sympathectomized for hypertension (24).

The untoward sequelae of a differential spinal block are much the same as those of the full spinal block. It is usual to observe a fall in blood pressure as the procaine ascends to the higher reaches of the subarachnoid space (19, 20, 21). This technique has been used in over one hundred patients for varying purposes related to the study of autonomic function especially hypertension. The fall in blood pressure has always been readily controlled by placing the patient in the head down position when it became advisable to do so. Nausea and vomiting may occur and cease soon after discontinuing the infusion. Spinal headache occurs as after any lumbar puncture. One patient had mild meningeal irritation for 2 days following a differential block. No other serious sequelae have occurred.

It is conceivable that the increase in bowel activity engendered by a spinal block in a patient with mechanical intestinal obstruction may result in a perforation. However the widespread use of spinal anesthesia for surgery on obstructed patients is evidence of the relative safety of this procedure.

A long enough period has not yet elapsed to allow of the critical evaluation of the merits of sympathectomy in these patients. It is hoped however that the procaine block of visceromotor fibers to the intestinal tract will provide a degree of prognostic accuracy for visceromotor disorders which the block of vasomotor fibers provides in vasospastic disease.

CONCLUSIONS

1. Visceromotor fibers to the intestinal tract are of about the same size and degree of mye-

lination as other sympathetic efferent fibers in so far as this similarity is indicated by their relative susceptibility to procaine hydrochloride.

2 Block of sympathetic efferent fibers to the intestinal tract was followed by a definite increase in propulsive bowel activity and co-ordination of transport in 3 of the 5 patients studied and a probable alteration in bowel activity in the remainder.

3 Visceral afferent fibers subserving the sensation of distention are relatively large myelinated axones in so far as this is indicated by their relative refractoriness to procaine hydrochloride. They are not blocked by that concentration capable of interrupting sympathetic efferents (vasomotor sudomotor and visceromotor) and fibers carrying the appreciation of pinprick.

4 Impulses traveling over autonomic nerves can contribute significantly to the production of a syndrome consisting of distention obstipation, tympanites, fecal vomiting and cramp-like abdominal pain which can be easily confused with acute, mechanical intestinal obstruction. This type of neurogenic obstruction may be sufficiently obscure to precipitate numerous abdominal interventions and the patient finally falls into that category labelled the multiple laparotomy syndrome.

5 The conventional type of full spinal block and a differential spinal block are of value in relieving this type of bowel obstruction and in helping to establish the diagnosis. The differential spinal block is more specific as an investigative tool inasmuch as the fibers carrying distention pain are not interrupted. The alteration of bowel activity is therefore presumably due to a block of visceromotor fibers. It has the added advantage of allowing the patient to use her abdominal musculature in expelling colon contents at the peak of intestinal activity.

6 Impulses arising in the autonomic nervous system may be important in colonic atony as seen in the adult since block of the visceral

efferents can greatly alter colon activity in such a patient.

7 It is of great importance to withhold medication when attempting to augment intestinal activity and transport by means of spinal anesthesia.

THE BIOLOGICAL CHEMISTRY OF WOUND HEALING

I The Effect of dl Methionine on the Healing of Wounds in Protein Depleted Animals

S ARTHUR LOCALIO M.D., Med. D.Sc., F.A.C.S., MARGARET E. MORGAN M.D. and
J WILLIAM HINTON M.D. F.A.C.S. New York, New York

THE tissues are dynamic structures with metabolic and catabolic phases proceeding concomitantly. The processes of tissue synthesis and destruction are chemical in nature. Proteins, nucleotides, lipids, carbohydrates, crystalloids, oxygen water enzymes, catalysts and other factors probably take part in these as yet poorly understood reactions. Following the infliction of a wound in a normal organism the chemical processes involved in tissue synthesis are accelerated and rapid healing results. In protein-depleted subjects these processes apparently are impaired and healing is delayed.

Howes and his co-workers (14) studied the effect of complete starvation on the rate of fibroplasia in wounds of adult rats and concluded that complete starvation did not alter the healing curve. However in young rats they found that complete or partial starvation did appreciably retard the rate of fibroplasia, and thus prolonged the proliferative phase and final healing. Clark noted that a diet high in protein shortens the lag period in the repair of experimental wounds. Harvey and Howes (13) noted no change in the lag period in protein fed rats, but the velocity of fibroplasia and the proliferative phases were stimulated. Thompson, Ravdin, and Frank showed that the hypoproteinemic dog is incapable of normal fibroplasia. Koster and Shapiro (17) and Koster and Kasman (16) have shown that hypoproteinemia is a factor in the faulty healing of wounds that eventuate in disruption. Localio, Casale and Hinton (20) stated that the lag period and the period of final healing were delayed in protein-depleted rats. Localio, Chassin and Hinton (22) showed that deple-

tion of the tissue proteins was a factor in human wound disruption.

It is generally agreed that in animals and humans, protein depletion adversely affects the healing wound. Healing although delayed and abnormal in the protein-depleted subject, nonetheless does occur. There are many other factors that affect wound healing these are reviewed elsewhere (20, 21) and are not a part of this study.

It has been shown that the delayed healing of wounds in protein-depleted subjects can be corrected by the administration of high protein diets and hydrolysates (34). Madden (23, 24) and Rose (29, 30) have demonstrated that humans and animals can be maintained in positive nitrogen balance by the administration of synthetic amino acids as the sole source of nitrogen. Rose has accomplished this by the use of nine amino acids which are essential to rat growth. Although all of these amino acids are essential for the maintenance of nitrogen balance it has not been determined if all of them are vital for wound healing. It is unlikely that all of these amino acids take part in the healing of a wound for some of the acids are necessary for functions not directly related to wound healing. A deficiency of lysine may cause menstrual irregularities in the female and a deficiency of arginine in the male is followed by a low sperm count. These and other symptoms not directly related to wound healing are listed by Albanese as due to deficiency of specific essential amino acids.

Hammitt (11, 12) in experiments done on the growth of the carrot root, has shown that there is an increase in the number of the root cells if the sulfhydryl (SH) group was added to the cultures. Baker believes that glutathione, a sulfhydryl compound is a growth stimulating substance. Croft and Peters (9, 10) and

others (3, 6, 26) indicate that in rats and dogs dl methionine spares nitrogen however this has not been confirmed for man (8, 15). Because it contains the sulfhydryl radical because it spares nitrogen in animals and because it is an essential amino acid, methionine was chosen as the first amino acid to be tested.

MATERIAL

Young white adult male rats of pure Wistar strain purchased from a commercial breeder were used in the experiments. The first group of 65 animals were normal controls. The second group of 63 animals were depleted and rendered hypoproteinemic by means of diet. The third group of 67 animals were depleted exactly as group 2. After 5 weeks of depletion and during the course of wound healing these animals received dl methionine (Table I).

METHODS

The methods used for the determination of the tensile strength of the experimental wounds have previously been reported (18). Aseptic wounds exactly 3 centimeters in length were made to the right of the mid line in the upper abdomen of the animals. The wounds were closed with interrupted sutures of No. 36 Pilling stainless steel wire. Animals were sacrificed daily from 1 to 10 days and the tensile strength of the wounds determined by dis-

tending the peritoneal cavity with air and measuring the bursting pressure of the wound in millimeters of mercury.

The control group of animals were maintained on a basal ration of purina chow. The second and third groups of animals were placed on a diet consisting of 10 per cent carrot powder, 5 per cent crisco, 3 per cent agar, 1 per cent salt water was permitted *ad libitum*. Vitamins were not added to the diet. The diet contained 0.23 per cent nitrogen. Animals in group 2 were maintained on this diet for 5 weeks and then were operated upon. Animals were sacrificed daily heart blood was withdrawn for total protein determination and the tensile strength of the wound was determined.

Animals in group 3 were depleted and tested as were those in group 2. However each animal received 150 milligrams of dl methionine dissolved in sterile distilled water administered subcutaneously daily for a period of 10 days. The last injection of methionine was given 24 hours before the animal was sacrificed. Animals destroyed on the tenth day received methionine daily starting with the day of operation. Animals sacrificed on the fifth day received methionine 5 days before operation and 5 days after operation. Animals sacrificed on the second day received methionine for 8 days before operation and 2 days after operation etc. In this fashion all animals had received a

Fig. 1 Mean tensile strength of abdominal wounds in normal rats, —x— hypoproteinemic rats —+— and in methionine-treated hypoproteinemic rats o—+—o.

total of 1500 milligrams of methionine 24 hours before they were destroyed. Methionine was not administered to any animal until 5 weeks of dietary depletion had been completed.

RESULTS

Table II taken from previously published work (19) lists the maximum tensile strength in millimeters of mercury that can be applied to the abdominal cavity of normal unoperated control animals. The limiting factor is the tensile strength of the pelvic peritoneum. At a mean tensile strength of 97.7 millimeters of mercury disruption of the pelvic peritoneum

TABLE III.—DATA ON NORMAL WOUNDS

Days postoperative	No. of animals	Mean pressure necessary to cause disruption	Site of disruption
	5	65	All in wound
	5	64	All in wound
3	5	82	All in wound
4	5	75	All in wound
5	5	87	One in wound
6	5	96	None in wound
7	5	96	None in wound
8	5	98	None in wound
9	5	91	None in wound

occurs and higher mean pressures therefore cannot be applied to the wound. In animals operated upon where disruption has occurred in the pelvic peritoneum and not the wound, we have considered the wound healed. In some of the hypoproteinemic and di-methionine animals, the pelvic peritoneum disrupted at pressures appreciably less than 97.7 millimeters of mercury. In these wounds the tensile strength is that recorded, plus an unknown.

Table III from a previous publication (19), lists the mean tensile strengths of the wounds of normal operated animals. Tables IV and V list the weight loss, total proteins, and the mean tensile strengths respectively of wounds of the protein-depleted animals and of the protein-depleted animals receiving methionine.

Figure 1 is constructed by plotting the mean tensile strength of the wounds of normal animals, of the protein-depleted animals, and of the protein-depleted animals which received methionine. The comparative lag periods for the 3 groups are 3 days for the normal, 7 days for the protein-depleted and 1 day for the protein-depleted plus methionine. Table VI lists the percentage of wounds that could be disrupted in each of the three groups for the total period of 10 days of the experiment: normal 37 per cent, protein-depleted 73 per cent, methionine 36 per cent. The number of animals in each day in the three series is not strictly comparable. However the differences between the methionine-treated and untreated depleted animals is so great that the minor differences in the numbers of animals are not

significant. Statistical comparison of the normal and protein-depleted rats (Table VII) shows a significant difference in the tensile strength of the wounds between the normal and the protein-depleted animals, from the second to the ninth days, the wounds in the protein-depleted rats being significantly weaker than in the normal.

Similar statistical comparison between normal animals and methionine-treated depleted

animals indicates that the tensile strength of the methionine wounds is significantly less than the normals, on the first, sixth, seventh eighth and ninth days. However on the sixth seventh and ninth days no wounds disrupted. On the eighth day, two wounds disrupted. Since the tension required to produce a rupture of the pelvic peritoneum in the methionine animals is less than normal a fair comparison of wound strengths on these days is not possible.

On the second fourth and fifth days the period of proliferation, there is no significant difference and on the third day the methionine-treated wounds had a significantly greater tensile strength.

Table IV lists the statistical comparison of the hypoproteinemic animals untreated and treated with methionine. The tensile strength

of the methionine-treated wounds is significantly greater on all days from the second to the tenth except the eighth. On this day the methionine treated wounds are not significantly stronger. However the *t* value noted was 2.54 which is only 0.41 from a critical level which would indicate a statistically significant difference.

DISCUSSION

Wound healing in the protein-depleted rat proceeds with a prolonged lag period a prolonged proliferative period and delayed final healing. These results are in keeping with previous data (10) and coincide with numerous clinical observations (28).

The data further indicate that in protein-depleted rats the administration of one amino acid dl methionine can shift the curve of healing toward normal in spite of the fact that the animals are maintained on a depleting

diet, and they remain depleted as shown by the level of the total proteins. The lag period of methionine treated rats appears shorter than normal. The proliferative period does not follow the normal curve for there is little gain in tensile strength between the fourth and eighth days. However since many of these methionine wounds did not disrupt no fair estimate can be made of the wounds maximal tensile strength on these days. A comparison of methionine-treated and untreated animals shows a marked difference between lag pe-

riods, and it is only during the eighth day when the proliferative period of the untreated hypoproteinemc animals gets under way that these two groups of wound strengths begin to approach each other.

It is unlikely that one amino acid can supply the building stones for so complicated a chemical structure as the proteins of the fibroblasts healing the wound. A working hypothe-

sis must be sought to explain our results. The depleted animals in this study demonstrate delayed wound healing yet the wound did heal eventually in spite of the fact that postoperatively the animals were maintained on a protein-deficient diet. The protein building stones for healing were not administered to these animals, and hence they must obviously have originated from within the animal or

ganism. Preoperatively the stores of protein in the liver (r), and tissues were largely depleted hence we may assume that Nature in her desire to heal the wound has called upon the proteins of other cells for material. Mason (25) has stated that 'the urge to heal is equal to the urge to live. Nature will surmount all obstacles to close a wound'. Morgan in 1906 (27) showed that a starved salamander could regenerate an amputated limb as rapidly as a well fed animal. Regeneration occurs at the expense of other cells of the organism and the starved animal suffers atrophy of all its organs.

How can we account for the results obtained following the administration of dl methionine? Dl methionine must supply to the wound some factor which is not readily available or not available in sufficient quantities in the materials which the organism is able to supply to the healing wound. Dl methionine is the only essential amino acid containing the sulfydryl radical. If we reason that the sulfydryl (SH) radical is the chemical group that the depleted organism cannot supply to the healing wound in sufficient quantities and that without it the lag period of wound healing is delayed then we must search for a local wound function for the sulfydryl radical.

Barron and Singer have shown that there exists in a protein molecule certain bonds and groups in the side chain without whose integrity enzyme activity does not exist. Of these groups the electronegative sulfydryl (SH) group has been shown to be of much importance. They have shown that many of the reactions of the metabolic cycle are catalyzed by SH enzymes. Further that chemical blocking of the SH group of these enzymes with alkylating agents iodoacetamide mercaptide-forming agents, and organic arsenicals causes inhibition of enzymatic activity. The addition of excess SH groups in the form of glutathione dispels the inhibition and enzyme activity proceeds. Stevenson and White in an experiment in rat growth showed that the administration of iodoacetic acid to the intact animal interfered with growth. They believe this to be due to the inhibition of SH enzymes. The addition of l-cystine l-homocystine and dl-methionine all of which supply SH groups permit growth to proceed unhindered. There-

fore since chemically many of the metabolic enzymes can be inactivated by blocking of the SH groups with suitable compounds, and since rat growth can be arrested similarly and since wound healing and growth are closely allied processes we offer the following as a working hypothesis: the protein depleted animal, although able to obtain building stones for healing from sources within the body cannot obtain a sufficient number of sulfydryl (SH) groups from these sources. Dl methionine supplies these SH groups to the depleted animal and wound healing can proceed in a more nearly normal fashion. Further the SH enzymes appear to exert their most important function during the early stages of healing. Without this enzyme activity the lag period of healing is prolonged with it is shortened.

Experiments are now in progress to test the effect of other amino acids and of SH groups of other compounds on wound healing. The effect of dl methionine in the healing of wounds in the depleted human is also being studied.

CONCLUSIONS

1. Protein depletion in rats causes a prolonged lag period, a slowed proliferative period, and a delay of final healing.
2. Parenteral administration of dl methionine to protein-depleted rats shifts the curve of wound healing toward normal. The lag period is decreased, final healing is accelerated in spite of continued protein depletion.
3. A hypothesis is outlined indicating that the sulfydryl (SH) radical is deficient and not readily available to the wound of the protein deficient rat, and deficient SH enzyme activity may be one of the reasons for delayed healing.

TUMORS OF THE TESTICLE

HANS R. SAUER, M.D., ERNEST M. WATSON, M.D., F.A.C.S. and EUGENE M. BURKE,
Buffalo, New York

THE diverse views expressed by various authors in attempting to classify testicular tumors have not made the discussion of this subject easy. A study of the literature indicates that various investigators are using different terms for the description of identical lesions and on the other hand, identical terms are being used for the description of different types of tumors.

The inadequacy of some of the heretofore advanced classifications is an undisputed fact. Pathologists and clinicians alike have applied a variety of descriptive terms to various types of testicular tumors and the detection of some unusual cell elements in certain neoplasms has often induced an investigator to complicate the already existent classification by the introduction of new subclassifications. This fact has resulted in the creation of cumbersome and at times confusing nomenclatures.

However it appears that recent investigations may have contributed materially to clarify our conception of the clinical and histopathological aspects of the disease. During the war it was possible to study a large number of patients with testicular tumors at various United States Army Hospitals and an even larger number of specimens at the Army Institute of Pathology.

Friedman and Moore, who had the opportunity to study 922 testicular neoplasms at the Army Institute of Pathology, have advocated a simplified classification which if found feasible would contribute greatly in establishing a common understanding among pathologists and urologists. They arrived at the conclusion that only 4 basic structural patterns were encountered in the majority of all tumors of the testicle. These cell patterns were described as seminoma, embryonal carcinoma, choriocarcinoma and teratoma

which may occur either alone or in combination. It was found that 96 per cent of the 922 cases fell into one of these categories. 3 per cent were considered too rare to be classifiable and 1 per cent consisted of interstitial cell tumors. In accordance with these statements the following implied classification was suggested: (1) seminoma, (2) embryonal carcinoma, (2a) choriocarcinoma, (3) adult teratoma, (4) teratocarcinoma or teratosarcoma.

PATHOLOGY

In adopting this classification we grouped our cases according to the following criteria:

Seminomas are monocellular tumors which consist of rounded polyhedral cells. Clear cytoplasm is the rule but variants with dark staining cytoplasm may occur. The hyperchromatic and irregular nuclei are usually centrally located and their chromatin is evenly distributed. Seminomas grow in solid sheets although a pseudoglandular appearance may be simulated as a result of separation of tumor masses by trabeculation of connective tissue. Lymphoid stroma may be absent or present in various amounts within the tumor bed (Fig. 1).

Embryonal carcinomas are tumors composed of embryonal type cuboidal or columnar cells which are larger than those of seminomas. The nuclei are large, their location within the cell varies and their chromatin is distributed in irregular masses. The differentiated part of the tumor is glandular in character often assuming papillary formation; however the undifferentiated areas are found to grow in solid sheets. In many cases embryonal carcinoma is associated with seminomatous tissue. Both cell types may then be found growing apart or closely intermingled. It is commonly observed that embryonal carcinoma invades seminoma tissue aggressively while it is found that seminoma respects tissue planes as it enlarges. Also choriocarcinoma ele

From the Roosevelt Park Memorial Institute (Dr. Louis C. Kram, Director) and the Department of Urology, Medical School, University of Buffalo, Buffalo, New York.

Fig. 1. Seminoma.

AGE

The average age in our series of 202 patients was 33 years. However it was found that patients with seminoma belonged to an older age group (38.9 years, average) than those with embryonal carcinoma or terato-

Fig. 2. Embryonal carcinoma.

carcinoma (29.9 years, average). Over two-thirds (67.9%) of our patients were between 20 and 40 years of age. It was also noted that testicular tumors in patients under 20 years of age were more commonly encountered in cases of embryonal tumors (10%) while they

somewhat similar case in which the thyroid was the site of the primary lesion. In 1 instance we even found that painless tumefaction in both testicles was the first manifestation of an acute leukemia. Metastatic tumor growth in the testicle has lately been detected more often following the introduction of castration for the treatment of prostatic cancer.

Exploratory operation and not watchful waiting is the procedure of choice if the diag-

nosis is in doubt. In no cases should biopsy or needle puncture be resorted to as a means of establishing the diagnosis, because such a procedure would destroy the continuity of the capsule and facilitate dissemination of tumor cells.

More serious diagnostic difficulties are encountered at times, if the tumor arises in an undescended testicle. Particularly in a patient with an intra-abdominal testicle the neoplasm may assume considerable size be-

Fig. 6 Schematic drawing showing that lymphatics of the testis drain to abdominal-aortic and external iliac lymph nodes.

fore it produces symptoms. Pain in the lower abdomen and groin represent the usual manifestations but there are certain cases in which the primary tumor remains symptomless and the first and only evidence of the disease is produced by the development of distant metastases. Under these conditions, it is often difficult to recognize the nature of the disease. In any case malignant degeneration of an undescended testicle should be included in the differential diagnosis of certain cases of metastatic carcinoma of unknown primary origin especially when metastases are found in the retroperitoneal space lungs or left supraclavicular region (Fig 5 a b c d). A positive Aschheim Zondek test may be of value in the establishment of the diagnosis in certain cases however in others an intra-abdominal testicle cannot be definitely identified as the site of the primary tumor before postmortem examination.

METASTASIS

Metastatic spread of the disease occurs almost invariably by way of the lymphatics (Fig 6). Rouvière has demonstrated that the lymph trunks of the testicle ascend along

Fig. 7 Direct extension of testicular tumor into scrotum.

the blood vessels of the spermatic cord. At the crossing point of spermatic vessels and ureter the lymph vessels become separated from the internal spermatic artery and empty into the abdomino-aortic nodes. From there further dissemination may take place by way of the thoracic duct with potential involvement of mediastinum lungs, supraclavicular nodes etc. In addition a connection of testicular lymphatics and external iliac nodes has been described however it has been pointed out by Rouvière and others that these lymph vessels are not always present. Since there exists no connection between testicular lymphatics and inguinal nodes, it must be concluded that metastatic involvement of these nodes can occur only as the result of direct extension of the primary tumor into scrotal tissues (Fig 7).

When searching for possible metastases, the general pattern of metastatic dissemination must be kept in mind. While metastatic involvement of superficial lymph-bearing areas is readily detected and while metastases to lungs or mediastinum are quite reliably demonstrated by x ray examination some difficulty may be encountered in recognizing possible retroperitoneal metastases. Excretory urography which in certain cases must be supplemented by retrograde pyelography is often essential accurately to complete the diagnostic procedure since lateral displace-

TABLE III.—SITE OF METASTASES IN 117 PATIENTS

	Semi-noma 47 patients	Embryonal carcinoma 50 patients	Teratocarcinoma 4 patients	Miscellaneous 6 patients	Total 117 patients
Paraortic nodes	56	30	0	2	87
Lungs	1	31	0	6	38
Gonads and spermatic cord	15	8	1	3	27
Left supraclavicular nodes		0	2		2

Bones	1	3			4
General carcinomatosis	0	10	7	1	18

ment of the ureter may indicate the presence of pre-aortic node involvement where palpation fails (Cahill)

Metastases were demonstrable in 117 or 57.9 per cent of our 202 patients. One hundred and eight of them had metastases at the time of admission and 9 developed metastatic lesions subsequently. The incidence of metastases was highest in the group of embryonal carcinomas (51 or 72.9% of 70 patients) which is consistent with their tendency to invade the adjacent structures aggressively. In contrast metastatic lesions occurred less frequently in the group of seminomas (47 or 50% of 94 patients) which often respect tissue planes as they enlarge.

In the over all picture of metastases the abdomino-aortic nodes were involved most frequently (87 cases) and no material difference was found in the frequency of their occurrence between the various types of testicular neoplasms. However there was a significant difference in the occurrence of parenchymal metastases. While metastases of seminomas remained confined to pre-aortic or iliac nodes in the majority of the cases, it was apparent that the parenchymal organs particularly the lungs were the site of metastatic lesions most often in cases of embryonal carcinoma, teratocarcinoma or chorioepithelioma. It ensues that general carcinomatosis was encountered more frequently in the latter group of cases (Table III)

TABLE IV.—TIME INTERVAL BETWEEN FIRST SYMPTOM AND DEVELOPMENT OF DEMONSTRABLE METASTASES

	Seminoma	Embryonal carcinoma	Teratocarcinoma	Miscellaneous	Total	Per cent
Under 6 mos.	16	30	4		50	44.5
7 to 12 mos.	0	5	4		9	17
1½ yrs.	6	2	2	1	11	24
2 yrs.	4	3	1		8	6.8
Over 2 yrs.	7	0	3		10	6.1
Not determined	4	2	1		7	6
	47	50	10	4	111	100

Further study of the occurrence of metastases indicated that the time elapsing between the onset of symptoms and first recognized metastases was less than 6 months in 52 or 44.5 per cent of the 117 cases. During the second 6 months the incidence dropped to 20 or 17.1 per cent. From then on a more definite decrease was noted (9.4% in from 1 to 1½ years, 6.8% in from 1½ to 2 years) but after a 2 year period metastases still occurred in 19 or 16.2 per cent of the patients. (In 7 cases the time interval could not be determined.) A seemingly significant observation was that metastases developed much earlier in the embryonal carcinoma group (58.8% of 51 cases during the first 6 months) than in the seminoma (34% of 47 cases during the first 6 months) (Table IV).

Of the 117 patients with metastases 95 (81.2%) died of the disease. The average duration of life after onset of symptoms was 23.2 months. It was longest in patients with seminoma (26.2 months) and shortest in the teratocarcinoma group (16.6 months).

TREATMENT

The generally accepted procedures in the treatment of testicular tumors are surgery and external irradiation. Preoperative deep x ray therapy of the primary tumor has been generally abandoned because it is considered of doubtful value for the following reasons: (1) Regional or distant metastases or both may develop while the patient is undergoing treatment. (2) a sterilizing tumor dose will render a histological diagnosis of malignancy

Fig. 6. Schematic drawing showing that lymphatics of the testicles drain into abdomino-aortic and external iliac lymph nodes.

fore it produces symptoms. Pain in the lower abdomen and groin represent the usual manifestations, but there are certain cases in which the primary tumor remains symptomless and the first and only evidence of the disease is produced by the development of distant metastases. Under these conditions it is often difficult to recognize the nature of the disease. In any case malignant degeneration of an undescended testicle should be included in the differential diagnosis of certain cases of metastatic carcinoma of unknown primary origin especially when metastases are found in the retroperitoneal space, lungs, or left supraclavicular region (Fig 5 a b c d). A positive Aschheim Zondek test may be of value in the establishment of the diagnosis in certain cases; however in others, an intra-abdominal testicle cannot be definitely identified as the site of the primary tumor before postmortem examination.

METASTASIS

Metastatic spread of the disease occurs almost invariably by way of the lymphatics (Fig 6). Rouvière has demonstrated that the lymph trunks of the testicle ascend along

Fig. 7. Direct extension of testicular tumor into scrotum.

the blood vessels of the spermatic cord. At the crossing point of spermatic vessels and ureter the lymph vessels become separated from the internal spermatic artery and empty into the abdomino-aortic nodes. From there, further dissemination may take place by way of the thoracic duct with potential involvement of mediastinum, lungs, supraclavicular nodes, etc. In addition, a connection of testicular lymphatics and external iliac nodes has been described; however it has been pointed out by Rouvière and others that these lymph vessels are not always present. Since there exists no connection between testicular lymphatics and inguinal nodes it must be concluded that metastatic involvement of these nodes can occur only as the result of direct extension of the primary tumor into scrotal tissues (Fig 7).

When searching for possible metastases, the general pattern of metastatic dissemination must be kept in mind. While metastatic involvement of superficial lymph-bearing areas is readily detected, and while metastases to lungs or mediastinum are quite reliably demonstrated by x-ray examination, some difficulty may be encountered in recognizing possible retroperitoneal metastases. Excretory urography which in certain cases must be supplemented by retrograde pyelography is often essential accurately to complete the diagnostic procedure, since lateral displace-

From then on a more definite decrease was noted (9.4% in from 1 to 1½ years, 6.8% in from 1½ to 2 years) but after a 2 year period metastases still occurred in 19 or 16.2 per cent of the patients (In 7 cases the time interval could not be determined.) A seemingly significant observation was that metastases developed much earlier in the embryonal carcinoma group (58.8% of 51 cases during the first 6 months) than in the seminomas (34% of 47 cases during the first 6 months) (Table IV)

Of the 117 patients with metastases, 95 (81.2%) died of the disease. The average duration of life after onset of symptoms was 23.2 months. It was longest in patients with seminoma (6 - months) and shortest in the teratocarcinoma group (16.6 months)

TREATMENT

The generally accepted procedures in the treatment of testicular tumors are surgery and external irradiation. Preoperative deep x ray therapy of the primary tumor has been generally abandoned because it is considered of doubtful value for the following reasons: (1) Regional or distant metastases or both may develop while the patient is undergoing treatment (2) a sterilizing tumor dose will render a histological diagnosis of malignancy

impossible and (3) certain types of testicular tumors are radioresistant.

Removal of the primary tumor immediately following diagnosis is always indicated regardless of presence or absence of metastases. This procedure is justifiable in the presence of metastases because it eliminates a potential source of infection and possible further dissemination of viable tumor cells from the primary focus.

In carrying out orchidectomy the spermatic cord should be freed, ligated and cut at the level of the internal inguinal ring following which the testicle and cord are removed *en masse*.

The value of routine retroperitoneal lymph node dissection as a means to improve results is still undecided. This type of operation has generally been carried out by Hinman (10) as well as Chevassu and others. In more recent years however with the improvement in the technique of irradiation therapy Hinman and Powell's (12) indications for the radical operation have undergone certain revisions in favor of radiation. This is especially so in the group of the more radiosensitive seminomas. Further support to this view is expressed by Nash and Laddy who state as follows: At present it (radical orchidectomy) seems to be reserved only for those patients who have malignant testicular tumors, who are in good physical condition without evidence of metastases and who have a radio-resistant tumor either with or without hormone in the urine.

Recent investigations by Lewis have stimulated a renewed interest in this controversial subject. During the past few years, Lewis had the opportunity to treat and follow up a large number of patients who were treated in three different ways namely orchidectomy plus irradiation, radical orchidectomy alone. Lewis, himself has stated that the follow up is as yet too short to permit definite conclusions but his investigations when completed will be of great value inasmuch as they are apt to determine the superiority of any one of the 3 methods in the treatment of the various types of testicular tumors.

For the present, we are of the opinion that the radical operation followed by x-ray therapy should be reserved in general for patients with the more radioresistant neoplasms, while simple orchidectomy plus irradiation should be employed in the group of radiosensitive seminomas.

Postoperative x radiation is indicated in all patients regardless of absence or presence of metastases. If no metastases are demonstrable, treatment is given over 3 separate areas namely lower abdomen and groin of the affected side, epigastrium, and mediastinum. Not less than 2000 r (with backscatter) should be delivered to the depth of each of these areas in cases in which histologic and biologic behavior suggests a radiosensitive neoplasm. But more than 2000 r should be delivered in tumors of the more radioresistant group.

If metastases are present at some other location these should be treated first. It often is then indicated to cross-fire through multiple fields in order to insure maximum irradiation effect at the site of the lesion. In these cases, it is important to keep in mind that treatment of the metastatic focus must be followed by irradiation of the groin, retroperitoneal space and mediastinum. In other cases in which metastases are found in mediastinum or abdomino-aortic nodes, irradiation should be given first to the lesion most distant from the primary tumor.

It is desirable in these cases to hospitalize the patients while they are under treatment and close co-operation between radiologist and urologist is essential in determining dosage, field size, and irradiation technique for each individual case. During treatment the effect of x ray therapy on metastases must be evaluated by daily examinations supplemented by x ray films when necessary and the plan of treatment must be modified as required by response or failure of therapy (Fig 8 a and b). In certain cases, it may also become necessary to direct additional treatment to a previously uninvolved area, because new metastases may develop while old ones are still being irradiated.

It is imperative in these cases to deliver in one course an adequate amount of irradiation.

Fig. 8. a, Extensive multiple metastases to both lungs before deep x ray therapy
b, Few metastatic foci remain, but elevation of right diaphragm suggests liver involvement.

to metastases in order to accomplish their disappearance when possible. While it is undoubtedly true that some seminomas show satisfactory response to dosages of less than 2000 r it has been our observation that others require more to obtain similar results (Table V). This statement is borne out by the fact that 42 or 79.2 per cent of 53 metastatic patients receiving less than 2000 r showed little or no response to treatment as compared to 9 or 19.1 per cent of 47 patients receiving in excess of 2000 r. These figures indicate that even in apparently radiosensitive tumors a dosage of under 2000 r should not be considered an adequate amount in the treatment of metastases. It has more recently become our practice therefore, to deliver larger dosages (2500 to 3500 r) in order more effectively to influence the course of the disease.

Our studies have led us to believe that success or failure of irradiation therapy particularly in metastatic cases depends almost entirely upon two factors namely (a) radiosensitivity or responsiveness of the tumor and (b) proper technique of irradiation and adequate dose delivered during one course of treatment. If metastases fail to respond or if they recur following a period of disappearance palliation only has been accomplished and little or nothing can be expected from subsequent irradiation therapy. The same statement applies for those patients who develop

metastases following an initial course of prophylactic deep x ray treatment (Nesbit). Also the introduction of supervoltage irradiation has not materially altered the prognosis in these cases.

The great majority of our patients were referred to the Roswell Park Memorial Institute after they had undergone simple orchiectomy elsewhere and only 14 of the patients were admitted with the primary lesion still present. Seven of them were nonmetastatic at the time of operation and the other 7 had distant metastases. The method or methods of treatment employed were consistent in general with the principles aforementioned.

END-RESULTS

The end results obtained in our series of 202 patients are summarized in Table VI

TABLE V --EFFECT OF RADIATION DOSAGE IN 100 PATIENTS WITH METASTASES

	Cure	Temporary disappearance	Marked temporary regression	Little or no response	Total
Under 2000r				2	
2000-3000r	7	1	3	40	5
3000-3500r		10	4	3	17
Over 3500r		4	3	6	13
	19	15	15	51	100

Complete failure 42 or 79.2% of 53 patients receiving under 2000r
9 or 19.1% of 47 patients receiving over 2000r

TABLE VI.—END-RESULTS IN 202 CASES OF TESTICULAR TUMORS

	Died of disease	Died other causes	Alive and well	Alive with disease	Lost trace of	Total
Seminoma	33		56		3	92
Embryonal carcinoma	46		23			70
Teratocarcinoma						27
Choriocarcinoma						3
Adult teratoma			3			5
Miscellaneous						3
	92	3	96		6	202

Over-all cures 96 or 47.5% of 202 patients

5 year cures 70 or 48.0% of 43 patients admitted before 3-31-41

year cures 15 or 31.7% of 47 patients admitted before 3-31-50

Ninety six patients are alive and well 2 are alive with the disease 95 died of the disease 3 died of other causes and 6 were lost trace of. This represents an over all cure rate of 47.5 per cent a 5 year cure rate of 48.9 per cent (70 of 143 patients admitted before December 31 1941) and a 10 year cure rate of 34.7 per cent (35 of 101 patients admitted before December 31 1936).

Our figures indicate further that regardless of the type of tumor death of the disease occurred most often during the first 2 years after onset of symptoms. The mortality rate for this period was 68.4 per cent (65 patients) with an approximately equal number of deaths occurring during the first (35 cases) and second year (30 cases). Hence the death rate showed a precipitous decrease to about 10 per cent for each of the following 3 years (9.4% during 3rd and 4th year 10.4% during 5th year). Only 3 patients who survived the 5 year period died of the disease after 6 7 and 11 years respectively. It ensues that any study based on 2 year follow up is subject to over 30 per cent error while any study based on 5 year follow up is subject to only 3 per cent error. Accordingly one is justified to conclude that any patient surviving 5 years and more can be considered almost safe from the possibility of recurrent disease.

An analysis of the end-results obtained in the various types of tumors revealed that the end results were most favorable in the seminoma group (59.6% over all cures) less favorable in the teratocarcinoma group (44.4%

TABLE VII.—SEMINOMA END-RESULTS

	Died of disease	Died other causes	Alive and well	Lost trace of	Total	Per cent
No lymphoid stroma	6		4			1
Little lymphoid stroma					21	55.1
Moderate lymphoid stroma	0		24		24	56
Abundant lymphoid stroma	6		17		23	56.1
	12		25	3	40	100

Over-all cures 56 or 59.6% of 94 patients

5 year cures 30 or 57.4% of 52 patients admitted before 12-31-41

year cures 15 or 44.5% of 40 patients admitted before 12-31-50

over all cures) and least favorable in the patients with embryonal carcinoma (31.9% over all cures). The number of our patients with choriocarcinoma, adult teratoma, or miscellaneous cell type tumor was too small to permit conclusions. The results in these cases were in agreement with well-known facts which indicate that choriocarcinomas offer an extremely poor prognosis, while adult teratomas have a comparatively high survival rate.

SEMINOMA

Fifty six or 59.6 per cent of our 94 patients with seminoma were alive and well at the time writing with a 5 year cure rate of 57.4 per cent and a 10 year cure rate of 44.5 per cent. It was found that the prognosis in this type of neoplasm was influenced to a large extent by the amount of lymphoid stroma encountered in the tumor bed. Of 35 patients with seminoma containing no or little lymphoid stroma, 18 or 51.4 per cent died of the disease and 15 or 42.8 per cent survived. In contrast, it was found that only 15 or 25.4 per cent of 59 patients of the other group were dead and 44 or 69.6 per cent were alive and well (Table VII). This confirms observations previously reported from this institution (Heger and Thibaudau).

It has been in the group of seminomas where irradiation therapy was found to be most effective. Although some of these tumors proved to be radioresistant, there were others which were not only radiosensitive but even radio-

TABLE VIII.—EFFECT OF SEMINOMATOUS TISSUE IN EMBRYONAL CARCINOMA ON PROGNOSIS

	Died of disease	Alive and well	Lost trace of	Total	Per cent
Embryonal carcinoma	30	9		40	57.5
Embryonal carcinoma plus seminoma	16	14		30	47.0
	46	23	1	70	100.0

Over-all cure in embryonal carcinoma, 9 or 22.5% of 40 patients.
Over-all cure in embryonal carcinoma plus seminoma, 14 or 47% of 30 patients.

curable. Permanent disappearance of metastatic lesions was attained by deep x ray therapy in 13 or 27.7 per cent of 47 cases. Eleven other patients responded either with temporary disappearance (6 cases) or marked temporary regression of metastases (5 cases).

EMBRYONAL CARCINOMA

Twenty three or 32.9 per cent of 70 patients with embryonal carcinoma were alive and well at the time of writing with a 5 year cure rate of 35.7 per cent and a 10 year cure rate of 26.8 per cent. However analysis of these results revealed that the prognosis in this type of tumor was significantly influenced by presence or absence of seminomatous tissue. The survival rate was 46.7 per cent in 30 patients with tumors comprised of embryonal carcinoma with seminoma while it was only 22.5 per cent in 40 patients with tumors consisting of embryonal carcinoma exclusively (Table VIII).

In contrast to the seminoma group our findings were that the amount of lymphoid stroma had no significant influence on the prognosis in patients with embryonal carcinoma, regardless of presence or absence of seminomatous tissue.

The response of metastases to irradiation therapy was generally poor in patients with plain embryonal carcinoma but appreciably better if the tumor contained an admixture of seminomatous cell elements. In 51 cases of metastatic embryonal carcinoma only 5 or 9.8 per cent showed permanent satisfactory response. Four of these patients had embryonal carcinoma plus seminoma and only 1 had embryonal carcinoma exclusively. Thirteen other patients responded with either tempo-

rary disappearance (7 cases) or marked temporary regression of the metastatic lesions (6 cases).

TERATOCARCINOMA

The number of teratocarcinomas in our series was not large enough in our opinion to permit of a conclusive evaluation. Twelve or 44.4 per cent of 27 patients were alive and well at the time of writing with a 10 year cure rate of 14.3 per cent. (The 5 year cure rate in this group was 72.7 per cent, but on account of the small number of cases no significance should be attached to this coincidental figure.) It was found that the type of malignant cell elements associated with the adult part of the tumor did not alter the prognosis in the cases of our series.

Teratocarcinomas are radioresistant with rare exceptions. Only 1 or 6.6 per cent of 15 metastatic patients responded with permanent disappearance of metastases, while 4 showed either temporary disappearance (1 case) or marked temporary regression (3 cases).

COMMENT

It was one of the principal objects of our investigations to determine to what extent it is possible to correlate histopathological findings and biological behavior of various testicular tumors. To this end we adopted the recently advocated simplified classification of Friedman and Moore as a basis for our studies although we were fully aware that this classification does not meet all the requirements to satisfy the embryologist, pathologist and clinician alike. Nevertheless, in spite of certain shortcomings, we considered this new classification helpful because of its simplicity and if generally accepted it might promote a more common understanding among various investigators.

We agree with Friedman and Moore that it is advantageous for practical purposes, to omit a comparatively small group of rarely encountered neoplasms from a commonly used classification because the inclusion of these rare types of tumors must lead to confusion. In general we have been able to confirm their observations which are that the great majority of testicular tumors follows 4

CORRECTION OF HYPOPROTEINEMIA BY THE ADMINISTRATION OF PLASMA AND BLOOD

J GARROTT ALLEN M.D., F.A.C.S., GEORGE BOGARDUS, M.D., WILLADENE EGNER, B.S.
and DALLAS B. PHEMISTER, M.D. F.A.C.S. Chicago, Illinois

SEVERAL recent authors consider that intravenous plasma therapy is not an efficient and practical means of elevating the plasma proteins in the hypoproteinemic patient (1, 3, 8, 11, 13). This point of view is reflected in Elman's (1) recent statement in which he concludes that "As long as the surgeons are confronted with the patient who cannot take and assimilate adequate protein nourishment through the gastrointestinal tract the parenteral injection of appropriate amino acid mixtures is the only method of preventing and correcting protein starvation during such periods." Further search of the literature however suggests evidence that plasma and blood may be of value for this purpose.

Holman, Mahoney and Whipple (9) reported that dogs on a nitrogen free diet, when given intravenous plasma and sugar were maintained in positive nitrogen balance. These animals metabolized the administered plasma without increased nitrogen loss although only 3 to 15 per cent of the injected plasma protein remained in the circulation 7 to 10 days after injection. They postulated that the remaining 85 per cent was recast as tissue protein without nitrogen loss. Specific human data of this type in which large and repeated infusions of plasma have been administered, are insufficient to permit definite conclusions as to the efficacy of plasma in elevating the plasma proteins, etc. In a recent editorial on blood plasma, however Snyder stated that "In wartime plasma was used extensively to correct and prevent hypoproteinemia—it became routine practice to give these patients 500 to 1000 cubic centimeters

of plasma daily besides the whole blood needed. Plasma protein determinations by the copper sulfate specific gravity method indicated that 500 to 750 cubic centimeters of plasma daily were sufficient to maintain a satisfactory level in most patients of this sort.

We are reporting the results of a study in which the hypoproteinemic patients were given large volumes of plasma in an endeavor to elevate the plasma proteins. Whole blood was sometimes given to correct anemia, but in all but 2 patients the greatest source of parenteral protein was plasma. These last 2 patients (1 and 8) were carried on plasma and blood to correct the preoperative hypoproteinemia later when the hypoproteinemic state reappeared in the postoperative period, amigen was given instead of plasma, and the relative efficiencies of these two sources of nitrogen as corrective agents, were compared.

METHODS

The plasma proteins were determined in duplicate by the macro-Kjeldahl method (3). The daily nitrogen loss in the urine and stool was determined by the micro-Kjeldahl procedure (5). When nitrogen loss was augmented by gastric aspirations or weeping wounds, these excreta were also taken into consideration. The hematocrit reading was made on heparinized blood centrifuged at 2,800 revolutions per minute for 20 minutes. Hemoglobin determinations were measured in the Evelyn colorimeter (4). Plasma volume was measured by the Evans blue dye method (8) samples being drawn at 10, 20 and 30 minutes after dye injection. Blood loss at operation was also considered, the principle of Gatch and Little being used (6). Erythrocyte and leucocyte counts were made daily.

Six of the 9 patients reported here were in hospital rooms where facilities for metabolic

From the Department of Surgery, The University of Chicago. This work was aided by grants from the Douglas Smith Foundation and Orlin S. A. Sprague Memorial Institute, The University of Chicago.

Presented at the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, New York, September 8-12.

Fig. 1 Case 1 No 402357 Plasma protein and plasma albumin record. Radical mastectomy Weight constant.

studies were available. All food items taken orally and parenterally were recorded in terms of grams of nitrogen, carbohydrate and fat. Various vitamin supplements were administered daily. Aside from the iron contained in the diet, no supplements of iron or liver were given. In these 6 cases it was possible during the greater part of the period of analysis to obtain complete collections of urine, stools, gastric juices, and to analyze these and the dressings for nitrogen loss. Three of the 9 patients were not on nitrogen balance studies.

Because of the critical nature of the hypoproteinemic patient, it was felt that where possible, oral feedings should be encouraged. In some cases either no food was ingested or the oral intake was meager. The amount of nitrogen taken by each patient has been tabulated and the route of administration is indicated.

PRESENTATION OF DATA

CASE 1 No 402357 A 56-year old housewife had carcinoma of the left breast with metastases to both axillae. Over an 18 month period she had received a course of x-ray therapy that resulted in necrosis of the left breast. Her weight had remained constant and her dietary intake fair.

Her hospital stay from the laboratory viewpoint was divided into seven periods, the nature of which are shown in Table I. The first period shows a prompt rise in the plasma protein concentration from

5.1 grams per cent to 7.0 grams per cent after 3 days of plasma administration totalling 4,400 cubic centimeters. At the end of this period the total circulating plasma proteins were increased from 97 grams to 182 grams. The plasma volume was increased from 1,970 cubic centimeters to 2,600 cubic centimeters and there was a positive nitrogen balance of 99 grams.

After radical resection of the left breast complete skin closure was not possible, so that the dressings were moistened by the serosanguineous drainage. This drainage, coupled with the excretion of both urine and stool nitrogen, averaged 4.6 grams per day for 9 days exactly offsetting the oral intake of 4.6 grams nitrogen per day which was the only source of nitrogen given during this period. The total circulating plasma proteins were reduced from 182 grams to 169 grams and the plasma protein concentration fell from 6.9 grams per cent to 5.9 grams per cent by the ninth postoperative day.

On that day the wound was covered with a dermatome skin graft. For the next 6 days her oral nitrogen intake was reduced to 2.1 grams daily as her appetite had waned. She entered into a negative nitrogen balance averaging 4.0 grams per day but without significant change in the total circulating plasma proteins or their concentration. Presumably her plasma proteins were being maintained at the expense of the body proteins during this period.

In an attempt to overcome the negative nitrogen balance, 5 per cent amigen and 5 per cent dextrose were given the average being 1,400 cubic centimeters (or 11 gm. of nitrogen) per day for 8 days. The amigen, combined with a small daily oral nitrogen intake resulted in a positive nitrogen balance of 17 grams per day. Despite this the plasma protein concentration fell from 5.7 grams per cent to 4.8 grams

Fig. Daily plasma protein and plasma albumin record in Case 1, No. 308633. A gastroenterocolic fistula followed gastroenterostomy and patient lost 30 pounds.

per cent. Plasma was then substituted for amigen and 1,000 cubic centimeters (or 9 gm. of nitrogen) a day were given for 4 days thereby restoring the plasma protein concentration from 4.8 grams per cent to 6.3 grams per cent and increasing the total circulating plasma proteins from 163 grams to 240 grams. The positive nitrogen balance was increased from a daily average of 1.7 grams to 6.8 grams. Three days later she was discharged at which time her plasma protein concentration still remained at 6.3 grams per cent (see Fig. 1).

CASE 2, No. 308633. A 29 year old male was admitted with a diagnosis of gastrocolic fistula of 10 months duration complicating a 21 ma ulcer following a gastroenterostomy for duodenal ulcer. Undigested food particles were present in the stools, and the patient had lost 13.5 kilograms (30 lbs.) in weight despite the fact that he had had a voracious appetite and had ingested large amounts of food. For convenience of presentation his hospital stay has been divided into seven periods, as shown in Table I.

The first was a control period of 4 days in which the patient was allowed a full oral diet. An average positive nitrogen balance of 1.3 grams was achieved, and the plasma protein concentration was elevated from 4.6 grams per cent to 5.0 grams per cent. The total circulating plasma proteins were also essentially unchanged.

During the second period of 6 days he was given daily infusions of plasma, totalling 7,000 cubic centimeters in addition to his oral diet. The positive nitrogen balance was increased from 1.3 grams per day to 14 grams per day. The plasma protein concentration was increased from 5.0 grams per cent to 7.1 grams per cent and the total circulating plasma proteins were raised from 235 grams to 355

grams. After closure of the fistula he received no nitrogen, either orally or intravenously for 4 days during which time he was given glucose and saline. The result was a negative nitrogen balance of 13.3 grams. Some of this negative balance was due to the presence of gross blood in the stool. During this time the total circulating plasma proteins declined from 355 grams to 306 grams and the plasma protein concentration fell from 7.1 grams per cent to 6.0 grams per cent. In the next, or fifth period, the patient was given feedings with an average daily intake of 8.2 grams of nitrogen for 7 days. The plasma protein concentration increased from 6.0 grams per cent to 6.3 grams per cent, but this increase was relative as the patient had been overhydrated and then dehydrated, as shown by the plasma volume reduction from 5,175 cubic centimeters to 3,840 cubic centimeters so that his total circulating plasma proteins actually fell from 306 grams to 239 grams. At the end of this period a subdiaphragmatic vagotomy was done in treatment of the ulcer and the eight day postoperative period was characterized by weight gain, a positive nitrogen balance of 2.3 grams per day and a decrease of the total circulating plasma proteins from 239 grams to 384 grams. He was discharged on the ninth postoperative day and 5 months later had gained 60 pounds. Daily changes in the plasma protein concentration are shown in Figure 2.

CASE 3, No. 401432. A 60 year old male was admitted to the hospital with a diagnosis of carcinoma of the stomach and a history of 27 kilograms (61 lbs) weight loss in 4 months. A subtotal gastrectomy was done and a transfusion of 600 cubic centimeters of blood was given during operation. No visible metastases were left behind. By the next postoperative day during which time he had received only glucose and saline intravenously.

Fig. 3. Plasma protein and plasma albumin record Case 3, No. 41,432. Patient had lost 61 pounds in 14 months. Subtotal gastrectomy was performed for carcinoma.

Fig. 4. Plasma protein and plasma albumin record in Case 4 No. 401,977. Cholecystectomy. Weight constant.

plasma protein concentration had fallen from 6.1 grams per cent to 4.9 grams per cent.

At this time nitrogen balance studies were instituted and the results are recorded in Table I. Both oral feedings and plasma infusions were begun and resulted in an average positive daily nitrogen balance of 6.5 grams. During this 6 day period he received a total of 7,700 cubic centimeters of plasma. His plasma protein concentration increased from 4.0 grams per cent to 7.0 grams per cent (see Fig. 3) and the total circulating plasma proteins were elevated from 152 to 245 grams.

During the second period, beginning the day after the last plasma infusions, all nitrogen was administered orally and averaged 11.5 grams per day.

Throughout this period a positive nitrogen balance averaging 5.9 grams was maintained and the total circulating plasma proteins and the plasma protein concentration were essentially unchanged. The patient was then discharged.

CASE 4. No. 401,977. A 67 year old female was admitted with a diagnosis of acute cholecystitis and cholelithiasis of 6 hours duration. These symptoms rapidly subsided and on the eleventh hospital day a cholecystectomy was performed. There was no history of weight loss nor was there weight loss during the first 11 days after operation had been performed although her hospital diet was protein poor. The patient was afebrile and the leucocyte count remained normal.

Fig. 5. Plasma protein, red cell count, hemoglobin, and plasma albumin, in Case 5, No. 135,655. Bleeding duodenal ulcer.

The postoperative period was complicated by an upper respiratory infection with coughing and a thrombophlebitis for which dicumarol was given beginning on the seventh postoperative day. On the ninth postoperative day her wound disrupted and was immediately closed. Two days later the plasma protein concentration was 5.3 grams per cent and on this day nitrogen balance studies were begun (see Table I). A total of 2,750 cubic centimeters of plasma was administered intravenously which increased the plasma protein concentration from 5.3 grams per cent to 7.0 gram per cent (see Fig. 4) and raised the total circulating plasma proteins from 95 grams to 210 grams. During these 2 days there was a positive nitrogen balance of 20 grams per day.

During the next 8 days she was given no intravenous nitrogen but her oral nitrogen intake remained good. A positive daily balance of 31 grams was maintained and the plasma protein concentration and the total circulating plasma protein levels were essentially unchanged.

CASE 5, No. 135,688. A 44 year old male was admitted with a diagnosis of a duodenal ulcer with intermittent bleeding for 1 month and perforation of ulcer sutured 17 days previously resulting in subdiaphragmatic abscess. After 11 days of study antibiotic therapy and blood transfusions totaling 3,600 cubic centimeters a trans thoracic drainage of the abscess was done. The infection repeated hemorrhages and low food intake had resulted in a reduction of the plasma protein concentration of 5.2 grams per cent.

Three days after the drainage operation nitrogen studies were begun (see Table I) and whole blood was transfused daily for 12 days excepting the sev-

enth and eleventh—totaling 7,200 cubic centimeters in an effort to correct anemia and hypoproteinem. Contrary to expectations the total blood volume determined daily before each transfusion for 12 days (omitting the fifth and sixth days) showed no increase until after the seventh day or not more than 500 cubic centimeters of blood had been given. This quantity of blood was approximately 1 per cent amount of his calculated blood volume (see Table IV). At the end of this time however it had increased only 900 cubic centimeters which is counted for approximately 15 per cent of the total amount transfused. Thereafter the blood volume remained between 3,300 and 3,500 (see Table II) until the patient was discharged 9 days after the last transfusion.

During the transfusion period an average daily positive nitrogen balance of 20 grams was maintained. The plasma protein concentration was increased from 5.2 grams per cent to 6.8 grams per cent, although the total circulating plasma proteins were not greatly elevated (78 gm. to 102 gm.). The daily average oral nitrogen intake during this period was 11 grams. Nitrogen balance studies were continued for 9 days after the last transfusion. A positive nitrogen balance was maintained and a raised 3.9 grams daily. The plasma protein concentration and total circulating plasma protein were essentially unchanged.

CASE 6, No. 106,174. A 75 year old female was admitted with severe debility, anemia, malnutrition and draining sacral decubitus ulcer 8 weeks after she sustained a subtrochanteric fracture of the left femur which was slowly uniting. She was studied through four periods (see Table I). Nitrogen balance was

Fig. 6. Plasma proteins and plasma albumin record in Case 6. No. 406,174. Unlimited fracture of left femur. Decubitus ulcer of sacrum. Severe debility.

urements were instituted and for 4 days the patient received whole blood transfusions totalling 1,050 cubic centimeters. A positive nitrogen balance of 12.8 grams was obtained although the plasma protein concentration remained essentially unchanged (Table I and Fig. 6) and there was little elevation of the total circulating plasma proteins and total plasma volume.

During the next 3 days the patient received only oral nitrogen which resulted in a slight negative nitrogen balance. There was no change in the plasma protein concentration or total circulating plasma proteins. During the next 4 days the patient received a total of 2,550 cubic centimeters of plasma which resulted in a return to a positive nitrogen balance and an elevation of the plasma protein concentration from 5.1 grams per cent to 5.6 grams per cent. The total circulating plasma proteins were raised from 142 grams to 179 grams.

For the next 13 days the patient received only oral nitrogen which again resulted in a slight negative nitrogen balance although the plasma protein concentration was maintained above 6.0 grams per cent. Due to the lack of suitable veins to procure samples, figures for plasma volumes and total plasma protein values are not available for this period.

CASE 7. No. 343,601. A 64 year old female had a sudden onset of severe epigastric pain and frequent emesis of small amounts of fluid 7 hours prior to admission. She had previously been in good health. An exploratory laparotomy disclosed acute hemorrhagic pancreatitis. Cholecystostomy was performed. On the seventh postoperative day with continued emesis the wound disrupted and was resutured. She was unable to take an oral diet aside from a small amount during the first week and was

maintained on intravenous injections of plasma, blood, glucose, minerals and vitamins. There was continuous drainage from the cholecystostomy for 10 days and from the pancreatic region until death.

The initial laboratory data showed a red cell count of 5.4 million and a white cell count of 17,000. The plasma protein level however was 4.6 grams per cent 2 days following operation. The blood and

cubic centimeters giving a daily average of 1,000 cubic centimeters plasma. Near the end of this period the plasma protein concentration had been elevated to 6.8 grams per cent, and the albumin was increased from 3.7 to 3.8 grams per cent (see Fig. 7). On the twenty first postoperative day she had a transfusion which was followed by jaundice and generalized edema persisting until death. Nitrogen balance studies were not made.

CASE 8. No. 362409. A 47 year old male had a gastroenterostomy performed for duodenal ulcer 6 years prior to admission here. One year following operation he developed diarrhea and began to lose weight. In the past 2 years he had lost 60 pounds in spite of an adequate diet. He was continued on a similar high caloric and high protein intake during his preoperative stay in the hospital. His stools however contained undigested food.

The initial laboratory data disclosed a plasma protein concentration of 3.4 grams per cent with an albumin level of 2.7 grams per cent. Eleven thousand cubic centimeters of plasma and 5,300 cubic centimeters of blood were administered over an 11 day period. The rapid rise in plasma protein level is seen in Figure 8 although 3,800 cubic centimeters of blood and plasma were given before any appreciable effect in the plasma protein concentration was achieved. A subtotal gastric resection gastrojejunostomy and partial colectomy were performed to eradicate the gastrocolic fistula and stoma ulcer. An unsuccessful attempt was made to sustain the plasma protein concentration by the use of amigen alone dur-

ing the first 10 postoperative days (see Fig. 8) although an average of 2,400 cubic centimeters of amigen was given daily during this time. However the plasma proteins fell from 6.2 grams per cent to 4.1 grams per cent. The plasma protein concentration rose when plasma oral feedings and amigen were again given. Nitrogen balance studies were not made.

CASE 9. No. 379854. A 74 year old male entered the hospital with a diagnosis of carcinoma of the cardiac end of the stomach. He reported a weight loss of 16 kilograms (35 pounds) in the previous 9 months.

TABLE II.—PLASMA PROTEIN CHANGES FOLLOWING PLASMA TRANSFUSIONS

6	37	4	42	179	71

Fig. 8. Plasma proteins and plasma albumin record in Case 8, No. 363,400. Patient lost 60 pounds in the years previous to admission.

The initial plasma proteins were 4.6 grams per cent with an albumin of 2.8 grams per cent. Five liters of plasma were administered over a 5 day period. At the end of this time the plasma proteins were 9.9 grams per cent. He was then maintained on a liquid oral feeding for 10 days and given 5 plasma injections totalling 1,400 cubic centimeters. A trans-thoracic esophageal resection was then performed during which 1,500 cubic centimeters of blood were given as replacement. Five days after surgery the plasma proteins had declined to 4.9 grams per cent. Five hundred cubic centimeters of plasma were given daily on the seventh, eighth and tenth postoperative

days. On the tenth postoperative day the plasma protein concentrations were 6.2 grams per cent (see Fig. 9). He was discharged on the thirteenth postoperative day. Nitrogen balance studies were made.

DISCUSSION

The plasma protein concentration of the patients reported in this study was significantly elevated by the administration of adequate amounts of plasma and blood. The ease with which the normal plasma protein concentration was restored, seemed more closely related to the extent of the starvation period than to the pretransfusion plasma protein concentration. For examples, in patients 1 and 4 whose nutritional states were relatively good a rapid rise in the plasma proteins was obtained when 2750 and 4400 cubic centimeters of plasma was administered over a 1 and 3 day period respectively. On the other hand in patient 6 in whom a long debilitating disease with a decubitus ulcer and marked weight loss had been present the rise in plasma protein concentration after the administration of 2550 cubic centimeters of plasma was slight. It was also difficult to elevate the plasma protein concentrations in patients 2 and 3 who had lost considerable weight (27 and 60 pounds) prior to their hospital admission. In these starved patients 4,000 to 5,000 cubic centimeters of plasma was given over 6 days before any elevation in the plasma protein concentration was detected. Similar difficulties were encountered in patient 9 (see Fig. 9).

TABLE III—BLOOD PROTEIN CHANGES FOLLOWING BLOOD TRANSFUSION

Patient No. 135688	Total grams blood protein transfused	Transfusion period in days	Total cir- culating blood protein pretrans- fusion	Total cir- culating blood protein after last transfusion	% of trans- fused blood incorporat- ed for by the increase in total circulat- ing blood protein
	1396		403	738	99

The total circulating plasma proteins were calculated at intervals on the basis of the circulating plasma volume and the plasma protein concentration. A knowledge of this figure is essential to the proper interpretation of the patient's response to the injected plasma or blood in the hypoproteinemic state since at times variations in the plasma protein may be more apparent than real. In fact, an elevation may result from plasma concentration when actually the total circulating plasma proteins may be reduced (see Table I patient 2 period 5).

A positive daily nitrogen balance was maintained during the period of blood or plasma therapy in all 6 patients on balance studies. In patients 4 and 5 this figure reached 20 grams per day. However 5 of the 6 patients on balance studies showed an increase in the total nitrogen excretion during the period of plasma or blood infusions, although this increased nitrogen excretion was relatively small compared to the increase in the total nitrogen intake. An average daily positive nitrogen balance of 12 grams was maintained during the period of plasma or blood administration. On the other hand the daily nitrogen balance during the periods immediately following the infusion period ranged from plus 4.0 grams to minus 13.0 (patient 2) and averaged minus 7.0 grams. This figure when patient 2 was excluded averaged plus 1.3 grams. However when compared with the figure of 12 grams of positive nitrogen balance obtained during the period of plasma or blood administration the degree of nitrogen retention induced by plasma and blood was striking. Moreover it would seem that there was little, if any latent increased nitrogen excretion at least for such periods as were studied here. The negative

6	127	560	785	3500	40	

or low positive balance figures which occurred in the post transfusion period were largely due to the fact that the oral nitrogen intake in patient 2 was zero. However patients 3, 4 and 5 were ingesting sufficient oral nitrogen to give them a positive nitrogen balance.

Of some interest is the continued plasma protein decline in patient 1 during amigen administration. The plasma protein concentration fell from 5.7 to 4.8 grams per cent in spite of a total nitrogen intake of 13.0 grams per day during this period although the total circulating plasma protein level was only reduced from 177 grams to 163 grams. A daily positive nitrogen balance of 1.7 grams was maintained in contrast to the 9.9 and 6.8 grams daily positive nitrogen balance during the 2 periods of plasma therapy (Table I patient 1 periods 1 and 6). Patient 8 showed a similar failure of amigen to maintain the plasma protein concentrations in the quantities administered. The normal plasma protein concentrations in both of these patients were again elevated when plasma and blood were given. In patient 1 where balance studies were made, there was only a 1.7 positive nitrogen balance during the period of amigen

administration. These findings are in agreement with Elman (2) and Meyer and associates (2) in so far as they found that patients could be maintained in positive nitrogen with amigen. However it was very difficult to elevate the plasma protein concentration at all even though large quantities of amigen were given (2,000 to 3,000 per day).

Data on the 6 patients on whom nitrogen balance studies and plasma volume measurements were made indicate that most of the transfused plasma could not be accounted for on the basis of increases in the total circulating plasma proteins. This point has been emphasized by Whipple and associates (9) and Elman (2) who found that only about 10 per cent of transfused plasma could be accounted for on the basis of an increased total circulating plasma proteins in dogs 1 week after the plasma administration. Our data suggest that man in the hypoproteinemic state reacts in a similar manner and that the larger amount of the administered plasma remained unaccounted for. It is possible as Whipple suggests that most of the transfused plasma proteins were recast as tissue protein without appreciable nitrogen loss.

An unexpected finding is that revealed by patient 5 who had generalized edema. This patient was given 5,200 cubic centimeters of whole blood over a 6 day period before there was an appreciable increase in total circulating blood or in plasma protein concentration, and

during this time the hematocrit reading was not increased even though a quantity equal to twice the patient's calculated blood volume was administered as transfused whole blood. During this same time the frequent calculations of the patient's blood volume failed to show an appreciable change from the initial pretransfusion level. However as these transfusions were continued, there was a rapid rise in the hematocrit reading in the total circulating plasma and blood proteins and in the total blood volume (see Tables III and IV). Weight loss, a disappearance of ankle edema, and a marked diuresis began after the third day of transfusions. The apparent failure of the patient's blood response to the transfusions of the first 6 days was not characterized by increased nitrogen loss, since there was a daily 20 grams positive nitrogen balance during this period. This figure fell to 4 grams positive balance during the 9 day study period which followed the transfusions. The oral nitrogen intakes were similar for both periods. Just what was the fate of the 5,200 cubic centimeters cannot be established from these data. The postoperative period was moderately septic for 7 days and there was a moderate discharge from the wound. Since there was no great increase in nitrogen excretion and since the transfused blood could not be accounted for by changes in blood protein, hematocrit reading or blood volume, some of it may have been held extravascularly possi-

bly as tissue protein. The amount of daily nitrogen lost through the wound ranged from 0.1 gram to 1.0 gram and did not appear to account for a major portion of the transfused protein.

States of anemia probably should also be considered as states of hypoproteinemia much in the same way that the plasma hypoproteinemic states are recognized. Whereas we corrected the plasma hypoproteinemia in our patients, there was always some degree of anemia which persisted unless blood was also given. A more complete picture would probably be obtained if the whole blood protein concentrations were considered in addition to the plasma protein concentrations. The hemoglobin concentration of 15 to 16 grams per cent in the normal person plus 6.5 to 7.5 grams per cent for plasma gives a total of 22 to 24 grams per cent for the total blood protein concentration. Since hemoglobin constitutes approximately two-thirds of the blood protein, a marked anemia may give a striking reduction in the whole blood protein even though the plasma protein is normal. The term hypoproteinemia probably should not be limited to lowered plasma proteins, but should apply to deficits in hemoglobin as well. Where anemia and hypoproteinemia coexist, both blood and plasma are necessary to restore the blood protein concentration to normal.

Plasma transfusions appear to induce an anemia out of proportion to that which might be accounted for by plasma dilution. The degree of this anemia, the total circulating hemoglobin and the grams per cent of hemoglobin before and at the end of the periods of plasma transfusions are shown in Table V. While the grams per cent of hemoglobin were appreciably decreased in most cases, the total circulating hemoglobin indicated that some of this anemia was due to blood volume changes.

The retarded recognition of the value of plasma for the purpose of elevating the plasma proteins may be attributed to the fact that most have used quantities of plasma too small to give appreciable changes (2, 14) in the plasma protein concentration. Our findings suggest that any less than 2500 cubic centimeters of plasma given over a period of 48

hours or longer is not likely to elevate the plasma protein concentration in the hypoproteinemic patient. Furthermore, our patients showed that an increase in the plasma volume occurred before the plasma protein concentration was increased and that the total circulating plasma proteins were often increased before the plasma protein concentration was elevated. For this reason several liters of plasma or blood may have to be injected before any elevation in the plasma protein concentration can be detected. During this early period most of the transfused protein including some hemoglobin, probably leaves the blood stream and possibly is converted into body protein as Whipple (14) has suggested. It is only after the plasma volume has been restored and the tissue proteins partially restored that the plasma protein concentration begins to rise.

SUMMARY

1 Plasma and blood were administered to a series of 9 surgical patients who had previously developed various degrees of hypoproteinemia and anemia.

2 The amounts of plasma usually given daily were large as measured by current practice but the amount of nitrogen given by this method was less than that advocated when protein hydrolysates are used for this purpose.

3 The increase in the plasma protein concentration was rapid after these quantities of plasma and blood were given and normal values were usually established within 5 to 7 days.

4 Nitrogen balance studies and plasma volume changes were made on 6 of these patients and showed that most of the transfused plasma probably left the blood stream within a day or two. That which could not be accounted for on the basis of an increase of total circulating plasma protein may possibly have been recast as tissue protein since there was little, if any evidence of a latent increased nitrogen excretion. The possibility that small increases of nitrogen excretion over a prolonged period of time may have occurred has not been detected in this study.

5 Larger amounts of plasma and blood were required to elevate the plasma protein

concentration in the more severely starved patient than in the better nourished one even though the plasma protein concentrations were reduced to similar levels in both groups.

6 Blood transfusions alone were administered daily with one exception for 11 days to 1 patient and as in the case of patients receiving plasma, the plasma protein concentration was restored to normal without evidence of latent nitrogen loss.

7 This work suggests that the fear of overtransfusion is unwarranted except where the cardiovascular reserve is reduced. It also emphasizes the importance of great enlargement of facilities for obtaining blood and plasma and the wisdom of using blood in some patients in place of plasma because of the gain in oxygen-carrying cells and the possible utilization of hemoglobin to form tissue proteins.

THE ELECTROCARDIOGRAM IN BILIARY TRACT DISEASE AND DURING EXPERIMENTAL BILIARY DISTENTION

Clinical Observations on 26 Patients

G B HODGE, M D Spartanburg South Carolina and A L. MESSER, M D,
Boston, Massachusetts

THE relationship and coexistence of biliary tract and heart disease have been of interest for many years. Data revealing a statistically significant coexistence of these two conditions are reported in the literature (Willius and Brown Breyfogle Laird Schwartz and Herman Walsh Bland, Taquini, and White and Tennant and Zimmerman) There is, however no conclusive evidence that the diseased gall bladder may cause heart disease Many physiopathological factors such as age, disturbed metabolism obesity diet and infection are common to both

Electrocardiographic changes in gall bladder disease have been reported by Fitz Hugh and Wolferth Clarke Breitwieser and Wakefield The abnormalities noted were T wave changes in significant leads, slurring and notching of the QRS complexes and elevation or depression of the RS-T segments Following gall bladder surgery improvement of the electrocardiogram or return to normal has been reported. However, it should be pointed out that electrocardiographic changes have been described in other intra abdominal conditions such as pancreatitis perforated peptic ulcer mesenteric thrombosis hemorrhage gastric distention and esophageal hiatus hernia (Gubner Murphy and Livezey Scherf and Klotz Gottesman Casten and Beller Morrison and Swalm and Gilbert, 5)

The electrocardiographic changes in biliary tract disease may be a result of viscerocardiac reflexes. Gilbert, Fenn and LeRoy (6) have demonstrated a reduction in coronary blood flow following stimulation of abdominal vis-

cera in animals. In patients with angina pectoris they were able to precipitate anginal attacks by distention of the stomach. Electrocardiograms taken simultaneously revealed abnormalities

Zollinger distended the gall bladder and common duct in 6 patients and studied visceral and referred pain In no patient did the pain simulate that of angina pectoris Ravdin Royster and Sanders distended the common bile duct in 2 patients in whom they were able to produce anginal pain Pain disappeared following release of pressure They reported that electrocardiograms taken during distention were negative

Hodge Messer and Hill distended the gall bladder of normal dogs. No significant changes in the electrocardiogram occurred other than an increase in the cardiac rate. However in animals with experimentally produced lesions of the coronary arteries significant abnormalities of the RS-T segments of the electrocardiogram occurred consistently

Since the relationship of biliary tract and heart disease is not clearly established this study was undertaken Electrocardiographic studies were made on 26 patients undergoing surgery of the biliary tract In 13 of the patients observations on pain respirations and blood pressure were made

METHOD OF STUDY

Routine electrocardiograms were obtained before and after operation on each patient. When abnormalities were encountered serial electrocardiograms with precordial leads of the C V series were obtained Electrocardiograms were taken during experimental biliary distention

Experimental distention of the biliary tract was produced in all patients Sterile normal

From the Departments of Surgery and Medicine, Duke University School of Medicine and Duke Hospital, Durham, N. C.
Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, September 8 to 11, 1947

TABLE I—ELECTROCARDIOGRAPH FINDINGS IN GALL-BLADDER DISTENTION DURING OPERATION

R F	35	Female	98	Flat T, low upright T and T ₃ Left axis deviation	79	Slight inversion of T. Axis deviation decreased	75	Stems arrhythmia No other change	68	T now low upright. T slightly more upright. No other change

saline solution was introduced under pressure through a cannula in the gall bladder or a rubber T tube in the common bile duct. Pressure was controlled by a water manometer apparatus and the maximum pressure used was 100 centimeters of water.

All of the patients had biliary tract disease. Twenty two had chronic cholecystitis with cholelithiasis. Three patients previously had had cholecystectomy for gall bladder disease with stones. At operation 1 had common duct calculi and in the remaining 2 no definite cause for their symptoms was found. Another

patient had a carcinoma of the head of the pancreas associated with chronic cholecystitis and cholelithiasis.

In the first group in which there were 14 patients with chronic cholecystitis and cholelithiasis gall bladder distention and electrocardiographic studies were carried out simultaneously at operation. All had the preoperative medication of morphine and hyoscine. Light ethylene-curare anesthesia was employed in each. Supplementary ether or cyclopropane was used occasionally but not during distention and electrocardiography. Control

Fig. 1. Case 8. A, Control record taken before anesthesia. B, After anesthesia. C, During gall-bladder distention. D, Following cholecystectomy.

electrocardiograms were taken before anesthesia after anesthesia before distention of the gall bladder during distention of the gall bladder, 10 minutes after distention and several days following operation.

In the second group of 13 patients distention of the common bile duct was carried out in 12 patients and the gall bladder in 1. Distention was performed 10 or more days after operation without medication or anesthesia. One patient in this group (Case 22) is also included in group 1 (Case 14). Observations were made on pain respiration and blood pressure. Electrocardiograms were taken before distention, with distention, and 10 minutes after distention. All had one or more preoperative and postoperative electrocardiograms.

RESULTS

The effects of anesthesia and distention of the gall bladder on the cardiac rate and electrocardiogram in group 1 are summarized in Table I. In 9 patients there was a decrease in cardiac rate after anesthesia and an increase in 5. During experimental distention of the gall bladder the cardiac rate increased in 10 patients and decreased in 1. There was no change in 3. Following release of pressure in the gall bladder 8 patients had a decrease in cardiac rate and 6 an increase.

After anesthesia premature ventricular contractions occurred in 2 cases (4 and 8) causing bigeminal rhythm (Fig. 1). This disappeared following cholecystectomy. One patient developed nodal rhythm which persisted during the operation (Fig. 2).

Three patients developed premature ventricular contractions during gall bladder dis-

tention, but this disappeared after release of pressure (Fig. 3). There were no cases in group 1 in which the P R interval or the QRS conduction time were prolonged during anesthesia or during gall bladder distention.

Electrocardiograms taken before anesthesia and after the preoperative medication of morphine and hyoscine revealed that 4 of the patients (Cases 1, 3, 8, and 14) in group 1 had records which were borderline or slightly abnormal due to depression of T 1. Three of these cases had normal electrocardiograms before the preoperative medication and 1 was abnormal. The electrocardiogram in 1 became normal after anesthesia (Fig. 3) and in 2 the records returned to normal following operation.

Four patients (Cases 6, 7, 9, and 14) developed significant T wave changes in lead I with anesthesia. Case 6 showed depression of the RS-T segment as well as the T wave in lead I suggesting myocardial ischemia (Fig. 4). In Cases 7 and 9 there was depression of T 1 and in Case 14 T 1 became slightly inverted.

During gall bladder distention the T waves in lead I were slightly depressed in Case 13 (Fig. 5) and slightly more upright in Case 3.

The results of biliary distention 10 or more days after operation in 13 patients are summarized in Table II. Eleven patients showed an increase in the cardiac rate during distention of the biliary tract while 2 showed a slight decrease. Premature ventricular contractions developed in 1 patient during distention of the common duct and in 1 patient a single premature auricular contraction occurred after release of pressure. There were no cases in group 2 in which the P R interval or the QRS conduction time were prolonged during distention. There were 2 cases (15 and 19) with abnormal electrocardiograms before distention.

of the common duct. In Case 15 T₁ changed from diphasic to low upright during distention (Fig 6). Case 19 showed no change. In 1 case with a normal record the T wave in lead I was slightly depressed during distention (Fig 7).

During distention of the common bile duct or gall bladder 11 of the 13 patients experienced pain. The 2 that did not experience pain had celiac ganglionectomy performed for biliary dyskinesia (Grimson Hesser Kitchen). One of these experienced only vague discomfort in the left upper abdominal quadrant.

In those having pain it was described as being severe and oppressive in character and located in the epigastrium. Four patients also complained of pain in the right upper abdominal quadrant and in 1 case there was radiation

of pain straight through from the epigastrium into the back. In no patient did the pain simulate that of angina pectoris. During distention and soon following distention 6 patients noted nausea and 2 patients vomited.

All patients who complained of pain during distention developed respiratory distress characterized by inspiratory inhibition. On release of pressure this symptom immediately subsided.

In 10 patients there was a rise in blood pressure during distention and a slight drop in 3.

In 5 of the patients interesting electrocardiographic changes occurred before and after operation.

CASE REPORTS

CASE 1. C. W., a 41 year old white female, was admitted to Duke Hospital on January 7, 1947 with chronic cholecystitis and cholelithiasis. She had typical symptoms of recurrent biliary colic, nausea, and vomiting of 1½ years duration. The only cardiac symptom that could be elicited was that of slight palpitation during attacks of biliary colic. There was nothing to suggest the anginal syndrome, and there was no history of digitalis or use of any medication prior to hospitalization. On physical examination the blood pressure was 120/80. She was of asthenic build and there was no jaundice. The heart and lungs were normal. Abdominal examination revealed only slight right upper quadrant tenderness. The heart was not shown to be enlarged by x ray examination. An electrocardiogram taken on

the date of admission was distinctly abnormal (Fig. 8). Serial records on January 10, 14, and 17 showed a progressive return to normal. Cholecystectomy was performed on January 22 under ethylene-chlorure oxygen anesthesia with supplemental cyclopropane and ether. Electrocardiograms taken during operation are shown in Figure 3. Following operation the electrocardiogram taken on January 23 and on February 2 became abnormal due to inversion of T₁. This was not significantly changed by exercise or

breathing pure oxygen for 5 minutes. A follow up electrocardiogram 6 months later was normal (Fig. 8).

CASE 6 O. E. S. a 55 year old white female was admitted to Duke Hospital on February 20, 1947 because of bilateral thrombophlebitis of the lower extremities of about 3 weeks duration. There was a history of intolerance to fatty foods with epigastric distress after meals of 4 months' duration. There was no history of precordial or substernal pain or exertional dyspnea. She had been given digitoxin before admission to the hospital because of edema of the lower extremities. On physical examination the

blood pressure was 130/80. The patient was obese and there was no icterus. The heart and lungs were not remarkable. The liver was enlarged and there was slight tenderness in the right upper quadrant. There was a subsiding bilateral deep thrombophlebitis of the legs. X-ray examination did not show enlargement of the heart. Serial preoperative electrocardiograms are shown in Figure 9. She received no digitalis during the first 16 days of hospitalization but was digitalized on March 8. An electrocardiogram on March 17 while on a maintenance dose of digitalis, showed evidence of return to normal. Cholecystectomy for chronic cholecystitis with cholelithiasis was carried out on March 19. The postoperative electrocardiograms gradually returned to normal and a record with extra precordial leads 436 months later was normal (Fig. 9).

CASE 14. R. E. F., a 55 year old white female, was admitted to Duke Hospital on April 15, 1947 because of pyrexia of unknown origin. There was no history of precordial or substernal pain or diminished car-

diac reserve. She gave a history of vague aching pain of the joints of all extremities and back as well as generalized aching of her muscles of about 18 months duration and bouts of recurrent low-grade fever for 12 months. On physical examination the blood pressure was 140/90. She was obese and there was no jaundice. There was some lordosis of the lumbar spine and pain on motion of both shoulders. Examination of the heart revealed slight acceleration of the aortic second sound and there was a soft systolic murmur at the apex. The abdominal examination revealed slight right upper quadrant tenderness. She had an inguinal hernia on the right. X-ray examination revealed the heart to be at the upper limits of normal in size and the spine showed osteoarthritic changes. A gall bladder visualization test revealed a nonfunctioning gall bladder. Preoperative electrocardiograms are shown in Figure 10. On April 30 a right inguinal herniorrhaphy, cholecystectomy, choledochotomy and choledochostomy were done under ethylene-chloride-ether anesthesia. The

H Record taken 4½ months later.

gall bladder showed chronic cholecystitis with cholelithiasis. Electrocardiograms taken during operation are shown in Figure 11. On May 13 distention of the common bile duct was carried out with electrocardiographic studies (Fig 12). An electrocardiogram taken 13 days postoperatively shows a return to the normal of the T waves in the limb leads (Fig 10).

CASE 15. E. R. G., a 69 year old white female was admitted to Duke Hospital on January 20 1947 because of colicky right upper quadrant pain of 18 months duration. A previous cholecystectomy had been performed in July 1946. She had been a known hypertensive for at least 4 years and had noted mild exertional dyspnea for 2 years and palpitation for 18 months. There had been no ankle edema and she had taken no digitals recently. On physical examination the blood pressure was recorded as 155/110. The patient was obese and slightly jaundiced with a blood bilirubin of 2.8 milligrams per 100 cubic centimeters. On January 28 1947 choledochotomy was carried out for calculi and 10 days postoperatively distention of the common bile duct was per-

formed. Electrocardiograms taken before and after operation are shown in Figure 13. An electrocardiogram taken 5 months after operation showed normal T waves in the limb leads with only slight flattening of the T waves in CV 5 and CV 6 in the precordial leads.

CASE 19. S. E. B. a 34 year old white female, was admitted to Duke Hospital on March 12 1947 because of nausea, vomiting and gaseous distention of 3 months duration. She had a cholecystectomy 11 years prior to admission. She had experienced mild recurrent attacks of bronchial asthma for 23 years. There were no symptoms of cardiac disease, and no recent use of digitals. On physical examination the blood pressure was 140/80. She was slightly obese and icteric. The heart was normal on physical examination and x ray examination showed no enlargement. On March 20 1947 exploratory laparotomy was carried out with lysis of adhesions. The common bile duct was explored. No stones were found. However a stenosis at the ampulla was dilated. On the fourteenth postoperative day the common bile duct was distended with simultaneous electrocardiography. The preoperative and postoperative electro-

cardiograms are shown in Figure 14. There was no change in the electrocardiogram during common duct distention other than an increase in cardiac rate.

DISCUSSION

It is evident from this study that several factors may affect the electrocardiogram. Depression of the T wave in lead I was observed in 3 cases (1, 3 and 8) after the preoperative medication of morphine and hyoscine. The

T wave changes in Case 1 may be related to the marked instability of the electrocardiogram exhibited during the entire period of hospitalization. In Case 3 the changes were of such slight degree that they could not be considered of significance. The T wave became upright in Case 8 at the end of operation.

Although T wave changes occurred in 4 patients following anesthesia, in only 1 (Case 6) did RS-T segment depression occur suggesting myocardial ischemia.

The slight depression of T_r during biliary distention in Cases 13 and 24 were of minor degree and are considered insignificant. The increase of amplitude of the T waves in lead I during distention was striking only in Case 15. Therefore, it is obvious that the electrocardiographic pattern is not predictable in biliary distention.

The electrocardiographic changes observed in 5 of the cases (1, 6, 14, 15 and 19) during the preoperative and postoperative period are not clear. The T wave changes recorded are similar to those observed by Fitz Hugh and Wolferth, Clarke and Brietwieser although

Fig. 3. Case 4. A, Control record taken before anesthesia. B, After anesthesia. C, During gall-bladder distention. D, Following cholecystectomy.

the majority of the patients reported by these authors were thought to have coronary artery disease. In none of the 5 cases reported here was there a history of the anginal syndrome, myocardial infarction or heart failure. The electrocardiogram did not show changes suggestive of myocardial infarction.

The T wave changes in Case 1 initially suggested digitalis effect, however this was not confirmed by history. The rapid return of the electrocardiogram to normal before operation

Fig. 14. Case 19. A, Electrocardiogram taken 4 months before admission to the hospital. B, Record taken on the day following admission to the hospital. C, Record taken on 6th postoperative day. D, Record taken 4 months after operation.

and the abnormalities following operation eliminated this possibility.

Case 6 presented a rather complicated picture. The digitalis she received before hospitalization can hardly account for the T wave changes observed during the first 2 weeks. After complete digitalization on the sixteenth hospital day the record appeared more normal.

Although there was a history of a low grade fever in Case 14 this was never higher than 38.2 degrees centigrade before operation. Later she became afebrile. This could hardly explain the electrocardiographic changes.

In Case 15 the electrocardiographic findings in lead I on the tenth postoperative day suggested left ventricular strain. However it is unlikely that hypertension could cause this abnormality to occur and disappear in 6 days. It is of interest that during distention of the common bile duct on the tenth postoperative day T₁ changed from diphasic to upright.

It is apparent that serial electrocardiograms are of the utmost importance when electrocardiographic changes are used as a criteria of cardiac improvement following gall-bladder surgery. Single records are of doubtful value since we have observed abnormal electrocardiograms to return to normal before operation and normal records to become abnormal after operation. There are no adequate electrocardiographic studies on the variations of the electrocardiogram in a large series of normal individuals. It is obvious that these electrocardiographic findings mirror changes in the myocardium however the nature of these is not clear. We do not feel that a diagnosis of coronary artery disease or myocardial infarction could be made on any of the above patients from the information obtained from history and physical examination.

SUMMARY AND CONCLUSIONS

In 26 patients with biliary tract disease the gall bladder or common bile duct was experimentally distended and electrocardiographic studies were made. The gall bladder was distended at operation in 14 patients and the common bile duct was distended in 12 patients and the gall bladder in 1 during the postoperative period. Disturbances in rate rhythm and the T waves are reported. The changes observed in the electrocardiograms during biliary distention in patients without clinical coronary artery disease were insignificant. This finding is similar to our previous observations on normal dogs (10). The effect of biliary distention on patients with the anginal syndrome remains to be investigated. Five of the patients showed changing electrocardiograms during the preoperative and postoperative periods. In no patient was the diagnosis of angina pectoris or myocardial infarction made and in no case did common bile duct or gall bladder distention cause anginal pain. Pain was more or less characteristic of that caused by biliary disease. All patients experiencing pain during common duct or gall bladder distention complained of respiratory

distress and in the majority there was a rise in blood pressure.

There is no definite electrocardiographic pattern in gall bladder disease. Changes in the electrocardiogram are variable and may be coincidental. Distention of the gall bladder or common bile duct may cause minor disturbances in rate and rhythm. T wave changes of a minor degree were observed but in no instance did these changes suggest a coronary pattern.

Conclusions regarding improvement in the cardiac status of patients following gall-bladder surgery are not justified on the basis of a single preoperative and postoperative electrocardiogram since serial records may show instability of the T waves.

GENERAL PLASTIC SURGERY

GENERAL plastic or reconstructive surgery has received varied recognition among surgeons. It may occupy an established position and an independent service in one medical organization while in another work that would fall into its category may be dispersed over several services depending upon the anatomical field into which the various lesions fall. But there is evidence that a plastic surgery department may relieve other services to a worthwhile extent.

To such a service would go patients falling into these groups (1) Injuries and deformities of the face and jaws that may alter the shape of the bony structure, or leave disfiguring scars of the soft tissue or result in abnormal function and physiology. These lesions include the work loosely called maxillofacial surgery (2) Injuries and deformities of any part of the body that require skin grafts or flaps, scar adjustments or surface tissue re-

adjustment. (3) Serious burns which may not be regarded initially as requiring ultimate restoration of surface but which are apt to do so and which from the start might be benefited by the opinion and care of a plastic surgeon.

Surgeons who work in an established field of general plastic surgery must necessarily rely on help from those trained in special anatomical fields such as nose and throat, eye, genitourinary, orthopedic and neurological surgery, and dentistry. In other words, the individual patient is the real consideration and whatever is best for him is the goal.

On the other hand, there are those who advocate that plastic surgery in a certain anatomical field such as nose and throat, eye, dentistry and orthopedics, should be done by specialists in this field. In some instances this method of care has produced excellent plastic surgeons in limited fields but there is a tendency for these surgeons to reach out into general plastic surgery and most surgical groups prefer to have their associates trained on general plastic services.

General plastic surgical services are comparable to general surgical services in affording groundwork training. Although often thought of as working in a limited field, the general plastic surgeon may do more different operations than other surgeons. It is noteworthy that practically all general surgeons are established as leaders because of work in some one field such as the thorax, heart, abdomen, tumor work or clinical research.

If progress is to be made, the plastic surgeon can never get away from the necessity of following and utilizing the results of research in pathology, physiology, chemistry, genetics, neuropsychiatry, etc. He utilizes general basic

advancements in the care and protection of patients undergoing surgery while he himself may have time for investigation only in his own field. However he can still be a pioneer or frontiersman in ferreting out simplification and directness in his general problems and in perfecting the technical skill that is so essential if patients are to have the greatest benefit. His co-operation with other services and other specialties based on anatomical grounds is one of his best contributions. The evident fact that deep healing can be no better than the surface healing has led the way for very close working relationship of the neurosurgeon and orthopedic surgeon with the plastic surgeon and because of plastic methods of preparing and repairing wounds many lives have been saved and much function restored, especially in the military services.

The military influence on plastic surgery has been great. Modern plastic surgery received its start in the last war and what was learned then was transferred to civilian use. During the intervening twenty five years, great strides were made so that the tables were reversed in World War II in that this civilian-gained knowledge could be turned back to the service for immediate use.

Within the United States Army and Navy during the recent war were built the largest plastic surgery services in the history of surgery and again young civilian surgeons gained knowledge in the services that can be given back to civilians. Before the war however the basis and possibilities of work had been established and the younger surgeons could go ahead under the guidance of civilian surgeons in the services.

A single item of interest in the change in plastic surgery from one war to another is the use of free skin grafts. In a three hundred page report from the last war no mention was made of skin grafts except as a part of one

sentence. Neither was any mention made of burns. In the recent war about one-third of the work in plastic surgery was with free skin grafts and about one-third for patients with burns. As one pioneer in plastic surgery resident in another country said, 'The things that are routine procedures in this war would have been considered fantastic in the last one.'

Much plastic surgery had been predicted on the repair of defects resulting from cancer, but the older patients with lax tissue available for repair do not present quite the same problem as the eighteen to twenty five year old youth who has had his face blown away in a second with destruction of features that he has developed for many years and counted on to carry him through life. These young patients deserve having the minimal of additional scarring and having repairs that would give the least possible residual deformity. They were forthright in their sacrifices and were humble in their demands—a challenge that was the best impetus to try to approach giving them what they deserved even though the surgeon realized his limitations in doing so. The annals of surgery display no greater courage and will to live on the part of the patients, or work and hope on the part of the surgeon than is found in the recent war in the doctor patient relationship and endeavor as seen in the blasted and burned and crushed patients and in their surgeons.

In this field of surgery it is difficult to get away from the doctor patient relationship. The demands of the patient through a long series of operations will not allow it in the first place, the clinical results cannot be good without it in the second place and there is some intangible feeling of the surgeon for his work that does not allow widespread mass production of the important details of repair. This might be called individual artistry but the results are so far short of artistry that the sur-

geon does not like to be stigmatized with it, or thought of as being able to make things perfect. He aims at function first, and with this goes a plan and effort to restore contour and smoothness to as near normal as possible.

Mass production does have to be done when hospitals are flooded with battle casualties or massive civilian catastrophes, but this involves mainly life saving measures, such as early grafting of burns. No matter how great the number of patients a nation has to deal with from the fallen soldier on the field to the finished product walking out of the plastic surgery center, there is no substitute for individual doctor patient relationship. This can not come from central direction but has to come from the surgeon and without it little success can be expected.

Plastic surgery has grown up and the field is enlarging. In this growth new ideas come from fields little known and some worn out edicts have been slowly abandoned. One school will use only local tissue another will advocate massive procedures for small defects. The young plastic surgeon will soon realize that he is only making substitutions for losses. He will learn early to use every bit of local tissue available, but he will also learn not to sacrifice adjacent features or function or nerve supply to avoid bringing in new tissue. It is one thing to utilize local tissue but the final *sine qua non* of a plastic surgeon is to be able to add more tissue from a distant part either as a free graft of skin or fascia or cartilage or bone or as a pedicle flap.

There is great interest among foreign surgeons in methods used by American plastic surgeons. The knowledge and the skill and the methods of plastic surgeons are available to all who show interest and seek advice and instruction so that there can be no just complaint of failure to pass on to others what has been found out by the experienced.

The place which plastic surgery holds is to a large part dependent on the surgeons themselves their teaching their ability to call attention to the problems at hand in short their ability to observe and record. There has been much overenthusiastic publicity of the possibilities of plastic surgery but most of it arises from individuals on the fringe or not even up to the edge, and the whole specialty has suffered. The public and often other doctors may have erroneous impressions of the possibilities and limitations of plastic surgery. On the one hand a patient may be told that the impossible can be accomplished and in no time at all, and thus come deep disappointments. On the other hand the simplest type of operative correction may be negated or omitted and the patient may go for months or years without a relatively simple procedure that would clear up the whole trouble. An example is a patient with ulcers of both legs who had been incapacitated for nine years and during this time no one seemed to think of a free skin graft. In one operation both legs were repaired with free skin grafts and the patient was returned to duty.

Plastic surgery has grown up it needs to grow further to a large extent this can only come from wide understanding but the challenge is to the individual surgeon who is called on to make substitution for deformed or lost normal physiology, and function and anatomy.

JAMES BARRETT BROWN

INDICATIONS FOR SURGICAL OPERATION AS AFFECTED BY CHEMOTHERAPY

THE introduction of such chemotherapeutic agents as the sulfonamides, penicillin and streptomycin into general use has led to the necessity of re-evaluating the place of surgical operation in the treat-

ment of a variety of infections. Conditions which formerly had come to be regarded as requiring surgical procedures of one sort or another for definitive treatment and were promptly referred to the surgeon now in many instances are treated early and late by the internist or general practitioner while antibacterial agents are being administered. In many instances abscesses and other complications of infection can be avoided by the prompt use of such measures supplemented with blood transfusions, anticoagulants and attention to the nutritional requirements of the patient. Furthermore there is no doubt whatsoever that under this treatment many patients with grave invasive infections show dramatic relief of symptoms with return of temperature to normal and restoration of appetite and sense of well-being. Two important and frequently ignored possibilities however must be kept in mind during chemotherapy for an infection. In the first place the infecting organism or mixture of organisms may not respond to antibiotics and valuable time may be lost if the therapy is hopelessly prolonged and in the second place even though symptomatic relief and striking general improvement is obtained nevertheless a mechanical lesion may have developed for which the only satisfactory treatment is surgical operation. In the one instance undue optimism and in the other a false sense of security lead to a delay in definitive surgical operation.

It should be remembered by internist and surgeon alike that it is the mechanical complications of infection which often require surgical operation. These may be pressure phenomena, loss of substance beyond the power of the organ to heal, crippling scar tissue persisting unabsorbable infected sloughs, fixation of a normally mobile or contractile viscus, narrowing of the lumen of a hollow viscus and the accumulation of exudates in body cavi-

ties. Though the infection may clear with chemotherapy obviously such complications will not and failure to appreciate this fact is unquestionably a common error nowadays.

Illustrations of these points come readily to mind. The symptoms of streptococcus or pneumococcus pneumonia with empyema may respond magically to penicillin therapy yet partial collapse of the lung, thickening of pleura and crippling of respiratory mechanism may persist. Unless evacuation of the empyema and re-expansion of the lung, as by early adequate surgical drainage, is effected the patient is not cured even though freed of virulent bacteria. In necrotizing lung abscess treated by penicillin the sputum will often diminish, the fetor subside, appetite return, cough improve and fever disappear. However if cavitation has occurred not only is the patient not cured but he faces the possibility of epithelization of the cavity, hemorrhage, exacerbation and spread of the infection, and involvement of brain or meninges. Not until the lung has healed is the patient well. Similarly the introduction of streptomycin in the treatment of pulmonary tuberculosis has not obviated the need for the usual measures for cavity closure when cavities exist. In chronic osteomyelitis with sequestration, cure is not to be expected without removal of necrotic bone though external evidences of infection may be controlled by chemotherapy. The general manifestations of renal suppuration may respond to chemotherapy but the function of the kidney may have been so badly impaired as to warrant nephrectomy. The pressure phenomena of epidural abscess of spinal canal or cranium may urgently demand surgical relief though the evidences of infection may otherwise have disappeared under vigorous chemotherapy. In femoral thrombophlebitis the infection may yield to penicillin and sulfonamides but the value of vein liga-

tion in the control of pulmonary infarction must still be considered

In that golden day when a specific chemical treatment for cancer is discovered and put into widespread clinical use, it can be predicted that some of the same considerations mentioned above will enter into the responsibilities of the physician. The secondary mechanical effects of the growth may be disabling or even fatal after all the cancer cells have been destroyed. The premium thus would place on early diagnosis and the need for restorative surgical procedures in the later cases are not hard to imagine.

The matter can be summarized with the statement that chemotherapeutic agents frequently will reduce or abolish the general evidence of infection, while a local mechanical problem amenable only to surgical treatment persists. Failure to recognize the distinction between relief of symptoms and restoration of normal function may lead to a serious delay in definitive treatment. JOHN D. STEWART

THE CHALLENGE OF THE SURGICAL FORUM

THE Surgical Forum has come to occupy an important place in the annual program of the Clinical Congress of Surgeons. There is need among surgeons for a program in which emphasis is lent the presentation of original work. A program formulated on this pattern is informative and stimulating.

Such a program representing essentially the fruits of the labors of the most promising young men in American surgical clinics and laboratories is destined to make its influence felt beyond the meeting halls of the Clinical Congress. Programs embodying new techniques correlating interphase specialty knowledge in the process of development including at the same time a perspective of new ap-

proaches to problems in the broad domain of surgery and outlining advances in related medical fields—such programs quicken the interest of participant and audience alike. What greater catalytic stimulus to productivity is there than an enlivened interest? If continued support is lent the Surgical Forum by American surgical clinics there is good reason to believe that the Surgical Forum will constitute an important means of giving directional growth to surgery in this country.

Surgery is making a valiant struggle to throw off the cloak of empiricism which has dominated its activity too long. And nowhere in the world has there been such a keen interest in experimental research as an approach to surgery as here. Moreover it needs to be said that distinguished surgical bodies in this country have been slow to admit young men who have given ample evidence of promise in the laboratory to active membership in such societies until they have demonstrated an equal proficiency in clinical surgery as reflected in the publication of clinical papers. Sterility of ideas and exclusiveness of membership in scientific societies are frequent and bad companions from which association mediocre programs come too frequently.

The American College of Surgeons is probably the largest organized group of surgeons in the world. It is fitting that they should undertake to sponsor participation in surgical programs of active young investigators whose work is frequently responsible in large measure for the improvements we note in surgery from year to year. Some of those young men bid fair to become the surgical leaders of tomorrow.

Man is gregarious. He meets with his fellow man of like interests to share experiences and profit by the exchange. A man who feels himself self sufficient and independent of his colleagues is denying himself the opportunity

for continued growth which association with stimulating colleagues affords. How quickly his work begins to reveal those telling traces of isolation! Attainment however great does not enable men to get on without assistance from helpful colleagues. Any man who has achieved any measure of success owes much to others. Many an idea is enriched by being communicated to another in that other mind the idea may take more definite shape than in the one from which it sprang initially. Oliver Wendell Holmes put it well. "That which was a weed in one intelligence becomes a flower in the other."

It is a stimulating and gratifying experience to come home from a meeting thrilled and exhilarated with the new thoughts and ideas ex-

pressed there and warmed in spirit by congenial good fellowship. Such occasions enrich our lives stirring us to strive to rise above mediocrity.

"Where'er a noble deed is wrought,
Where'er is spoken a noble thought,
Our hearts in glad surprise
To higher levels rise."

It is the professed intent of the Surgical Forum to try to bring before its audience each year the best creative thought and most original achievement in surgery. If the American College of Surgeons can meet that challenge in the broad domain of surgery and its specialties, it will contribute richly to surgery and bring laurels to itself.

OWEN H. WANGENSTEIN

THE SURGEON'S LIBRARY

THE BOOK SHELF

DOCTORS IN ARMOR

LEA A. RIELY, A.M., M.D., F.A.C.P. Oklahoma City, Oklahoma

HISTORY is merely the summation of biographical characters exerting pressure on a parallelogram of forces toward certain ends. These characters are stark individualists whose thinking molds sciences, nations, religions, etc. They are men of force and stamina, not to be swayed by argument or persuasion unless convinced of the falseness of their premises, and even then many are not converted. Were it not for these thinkers and doers, these knights in armor, conditions would be in a stalemate and we would settle down to a state of *laissez faire* complacency, letting progress perish.

Greek medicine was law and gospel during the Middle Ages until a few iconoclasts began to speak out against the then dominant and iron-bound ideas. Soon after Columbus steered his barks for unknown worlds, Martin Luther and John Calvin began to break the shackles of religious dogma, and Paracelsus those of Galenic doctrines. Publicly burning the works of Galen and Avicenna in a bonfire and lecturing in German out of his own experience, Paracelsus issued his polemics, both oral and written, against the then existing beliefs. For this he was driven from one town to another by professional enemies.

Emeritus Professor of Clinical Medicine, University School of Medicine.

During the Renaissance, first place belongs to this abused and abusive personage, Paracelsus, refused to recognize the cleft between medicine and surgery. He was erratic and unbalanced and often lost in incomprehensible mysticism, but he nevertheless enunciated principles in most vehement vernacular which furnished impetus to all rebellious spirits of the time and have since been incorporated into modern surgery. He exclaimed: "If God will not help me, so help me the Devil." Even his religion was nonconformist. "He who depends on the Pope rests on the sands. He who depends on Zwingli depends on hollow ground. He who depends on Luther depends on a reed. They all deem each above the other and denounce one another as anti-christs, heathens and heretics, and are but four pairs of breeches from one cloth."

Philippus Aureolus Paracelsus
1493-1541

Paracelsus died a natural death at forty-nine years of age in 1541 at Salzburg, not murdered by assassins instigated by those against whom he directed his trenchant diatribes. Modern research has proved groundless the current rumors of a tragic exit. Thus ended the life of one of those warring knights who at all times and in all countries rise above the common order of mentality. Never a one will compromise truth for political or social expediency.

The eighteenth century furnished two gentle knights, Auenbrugger and Laënnec, prophets not

Benjamin Rush
745 8 3

without honor save in their own countries. Not until their books were published abroad and then distributed at home did the embitterment against them soften down. Auenbrugger's *Neue Erfindung mittels des Anschlagens an den Brustkorb als eines Zeichens verborgener Brustkrankheiten zu entdecken* remained practically unnoticed until Corvisart took it up in 1808, one year before its author's death. Laennec's cylinder of paper has become the foundation of our knowledge of diseases of the chest, and his book, *Traité de l'auscultation médiate* unlike Auenbrugger's, was translated at once into many languages.

A noble knight of the nineteenth century was the great Lister whose lance was his advocacy of the antiseptic principle in the practice of surgery. His Glasgow, Edinburgh and London migrations were due, in part to harsh treatment by his confreres in these respective cities, but never was he deterred from his firm conviction of the efficiency of antiseptics. Had he not had a backbone of steel our conception of antiseptics would have lain dormant for years.

The War of the Revolution was responsible for bringing to the fore three doctors who donned their armor in the cause of medicine in America. The Medical Department of the University of Pennsylvania was founded by two stalwarts in

medicine, John Morgan and William Shippen, both educated at Edinburgh and both imbued with the ambition to teach medicine. Dr. Morgan became professor of the theory and practice of medicine, and Dr. Shippen held the chair of anatomy and surgery. It was Morgan who published the first appeal for good medical education in America. Both men became Surgeons General of the United States, both were accused of malfeasance both were deposed and both later secured acquittal. The charges against them were brought by disgruntled subalterns, who, blaming old revolutionary ideas of equality could brook no precedence in office. Both retired to private practice and to teaching.

A third American knight of medicine was Benjamin Rush, younger than Morgan and Shippen, but conceded the final authority of all three medical in Philadelphia. Rush, too, was a professor in the University of Pennsylvania, and was also physician to the Pennsylvania Hospital, and founder of the Philadelphia Dispensary and treasurer of the United States Mint. His highly original mind made him the foremost American clinician of his time. Called the American Sydenham and the Hippocrates of Pennsylvania, he won fame as a fighter in the Philadelphia epidemic of yellow fever in 1793. He was one of the signers of the Declaration of Independence and was once a general for the Middle Department under Shippen. Deserting Washington at Valley Forge he joined the infamous 'Conway' Cabal against Washington's Fabian policy, but at long last deeply regretted his withdrawal as being ill conceived and rash.

When yellow fever was endemic in Philadelphia in the seventeen-nineties, the man in charge of the pest house was a Celt from North Carolina by the name of Charles Caldwell. A graduate of the University of Pennsylvania, he had had Rush as a preceptor. Caldwell wore his armor continuously and left an autobiography full of venom and rancor. *Persone non grata* to Rush he was forced to emigrate plodding across mountains and through woods to Lexington, Kentucky then the Athens of the region west of the Alleghenies. There amid the great oaks of the forest, he hoped to start a university the equal, if not the superior to that of Pennsylvania. Dr. Robert Peter says that he never heard even in Europe such lectures as filled the halls of this backwoods university. But Caldwell did not find the waters smooth and glassy and arguments concerning the cause of death were sometimes more easily settled by duels than by postmortems. The two most prominent faculty members of the infant Transylvania

nia University were Daniel Drake and the first ovariologist Ephraim McDowell. Transylvania's diminishing standard and ultimate downfall were due to warring religious sects which alternately held and lost control. But it is due to Caldwell's erudition and choice picking of incubula from the book stalls of Paris after the Napoleonic wars that gave to Transylvania one of the finest libraries in the country.

Caldwell's conception of Drake was that of a gentleman highly distinguished for his powers of mind and useful attainments, and unfortunately not less so for his propensity to strategy and intrigue which marred his usefulness and darkened his fame. First after Hippocrates and Sydenham to do much for medical geography, Daniel Drake stands in a unique position in relation to the topography of disease. Of log-cabin immigrant stock, Drake received the first medical diploma issued west of the Alleghenies, a diploma handwritten by that pioneer of vaccination in the West, William Goforth. He took his academic degree from Pennsylvania in 1815, then became one of Osler's 'peripatetic physicians' ever at war with man. He moved no less than seven times during his combative life as a teacher and was the founder of the Medical College of Ohio and of the Medical Department of Cincinnati College.

Drake also founded the most important medical periodical of the West at that time, the *Western Journal of the Medical and Physical Sciences*. This periodical, which died of circulation troubles in 1838, contains Drake's famed essays on Medical Education. The height of Drake's literary attainments, however, is his book on the *Diseases of the Interior Valley of North America* which might be called the victory of his Thirty Years War. In his quest for firsthand knowledge, this tall thin hardy man would turn up at a trapper's fire and gossip about the local medical situation or would surprise the country doctors by 'pumping' them on the climatological influence on the prevailing illnesses. All in all, Daniel Drake was Western America's most famous knight errant.

One of the men against whom Drake aimed a celebrated invective was Transylvania's lame duck professor Constantine Samuel Rafinesque. Rafinesque might be likened to the White Knight in *Alice* always wandering from the orthodox way of medical men and always falling on and off the horse of quackery. This odd knight in armor was a doctor only by courtesy, and after

Daniel Drake
1785-1852

one year at Transylvania, went to Cincinnati and joined one Thompson and one Swain in the methods of herbalists. Rafinesque demurely admitted sixteen different attainments in which he particularly excelled.

These are but a handful of the doctors in armor who have wended their way through the Medical Kingdom. Full of chivalry for the ill and oppressed, they have fought famous battles against disease and ignorance, have thrust many a stout lance at the enemy in the Tournament of Death, keeping ever in their hearts the Quest of Healing.

REVIEWS OF NEW BOOKS

GREAT strides have been made in the management of the cancer problem in the past decade or two. The reason is obvious. Cancer is a disease that destroys approximately 185,000 individuals annually in the United States and on that basis it is fair to assume that another 500,000 are afflicted by it.

For many years a fatalistic attitude regarding cancer was almost universal both among the lay population and the medical profession. Due to this unfortunate attitude patients with cancer usually were seen and the condition recognized late as a result treatment was futile. However careful and persistent study of the nature of the disease its various types, and the process of its growth and dissemination brought forth evidence to form a premise which has been substantiated. The fundamental basis of this premise was that cancer is a local process in its beginning and may remain so for a short time. If it could be excised locally or destroyed by radiation in this stage cure would result. This took then was early recognition. This required the co-operation of the lay population and adequate training of the medical profession.

The American Cancer Society has done much in lay education during the past few years. In fact it seems that the lay population is becoming more cancer conscious than many of the medical profession. The busy physician has not time for and often no patience with the apparently well individual who fears cancer and yet the time the disease should be recognized is when symptoms are absent or very insignificant. Since the layman has been instructed regarding his needs the onus falls upon the medical profession to provide the service. It is recognized that certain internal cancers are difficult or impossible to detect in the early stages. Also it has been proved that in most instances elaborate and costly diagnostic procedures are not justified in the symptomless patient. However those anatomical areas of the body which can be examined readily without complicated procedures or special equipment are the site of about 60 per cent of all cancers. The justifiable conclusion is that physician must be made cancer conscious, develop skill in its early detection and make provision for adequate and proved therapeutic measures.

In recent years a number of excellent books on cancer and allied diseases have appeared. To this group can be added the recent work of Ackerman and Regato.¹ In surveying this book it is interesting to note that the authors assume a bold but absolutely just attitude on the cancer problem in its entirety.

¹CANCER: DIAGNOSIS, TREATMENT AND PROGNOSIS. By LAUREN V. ACKERMAN, M.D. and JOHN A. del REGATO, M.D. St. Louis: The C. V. Mosby Co. 1947.

Including the teaching of cancer to medical students, its early recognition and the therapeutic management.

The material is divided into two parts. The first part is devoted to phases of general interest. Chapter 1 includes an introduction to the subject and elaborates upon some of the issues mentioned previously. The incidence of cancer is discussed and early diagnosis stressed. A chapter is devoted to pertinent research work that has been done. This includes such topics as spontaneous tumors in animals, the rôle of heredity, carcinogenic agents, estrogens, and other hormones, the x-ray dyes, roentgen ray and ultra violet radiation, parasites, viruses, precancerous changes, carcinogenesis *in vitro*, chemical characteristics of neoplasms, transplantation of tumors, cancer theories and conclusions. A chapter is given over to pathology. This incorporates biopsy, fixation and staining methods, specialized procedures such as the aspiration biopsy, cell studies, frozen section work, differentiation between benign and malignant tumors, the spread of tumors and the like. A chapter is devoted each to surgery and radiation therapy of cancer. These five chapters are intensely interesting and contain a tremendous amount of pertinent information.

The second part is divided according to systems or organs. A chapter is assigned to each of the following: Cancer of the skin, cancer of the respiratory system and the upper digestive tract, tumors of the thyroid gland, tumors of the mediastinum, cancer of the digestive tract, cancer of the genitourinary tract, cancer of the male genital organs, tumors of the suprarenal gland, cancer of the female genital tract, cancer of the mammary gland, malignant tumors of bone, sarcomas of the soft tissues, cancer of the eye, Hodgkin's disease and the leucemias. The material in each chapter or subdivision is divided into anatomy, incidence, etiology, pathology, clinical evolution, diagnosis, treatment and prognosis. Under the heading of anatomy special attention is given to the lymph drainage. This is illustrated by excellent drawings and is a definite aid to the cancer diagnostician and therapist. Under treatment no great amount of detail of therapeutic technique is given. Those procedures, whether surgical or radiologic that have been found to be most successful either by the authors or others qualified are presented. Well controlled statistics are included. At the end of each chapter or subdivision is appended a bibliography.

The entire subject of cancer, exclusive of the nervous system, is extremely well presented, but some portions seem worthy of special attention. The chapter on cancer of the respiratory system and upper digestive tract merits praise. Tumors of the

nasal fossae, the maxillary sinus the floor of the mouth, the gingivae palate, nasopharynx, tonsil periepyglottic area, laryngopharynx and endolarynx are discussed in much detail. Tumors of these sites so often overlooked or neglected are deserving of special attention. This chapter of 281 pages is illustrated by 230 illustrations and three colored plates.

The chapter on the mammary gland does not seem quite to meet the standards set in the remaining portion of the book. Many of the illustrations depict far advanced stages of the disease. It might be wiser to focus the attention of the reader more upon the very early clinical signs of the disease. Dimpling of the skin or dimpling that can be elicited by special maneuvers is not mentioned.

This work of approximately 2100 pages with 745 illustrations and 42 colored plates is a welcome addition to the working library of every physician but should be of special interest to those interested specifically in cancer. The presentation is excellent the text is easy to read and the illustrations are illuminating.

The conclusions are sane not only from the standpoint of cancer in general as a highly destructive disease but in the admonition to the medical profession to prepare itself to meet the challenge confronting it.

JOHN A. WOLPER.

THE Handbook on Fractures by Duncan Eve¹ is well illustrated and contains valuable information recorded by the author from his experience of more than 40 years of trial and error in the field of fracture work.

All of the common fractures are well discussed and illustrated and a good number of complicated fractures are also included. This handbook will provide a ready reference in the treatment of most fractures. In a limited number of pages a complete discussion of all fractures cannot be made but the most important everyday fractures are included and discussed.

This volume deals entirely with the treatment of fractures. No attempt has been made to elaborate on the type of injury or signs and symptoms of fractures, but the entire emphasis is placed on the details of treatment.

In the preface the author includes one sentence that is intriguing. "There is no wrong way of treating fractures as long as success is achieved." While one does not entirely agree with all of the forms of treatment advocated by the author the above quotation justifies his method of treatment.

PRELIMINARY PLANS FOR 1948 CLINICAL CONGRESS THE BILTMORE HOTEL LOS ANGELES OCTOBER 18 TO 22 1948

THE thirty fourth Clinical Congress of the American College of Surgeons will be held in Los Angeles at the Biltmore Hotel from October 18 to 22 1948. Under the leadership of a strong and enthusiastic Committee on Arrangements, plans are under way for a complete and varied program for the 5-day meeting. The hospitals and medical schools will cooperate in scheduling operative clinics and demonstrations. Visiting surgeons will have ample opportunity to attend well arranged programs of many different kinds in the hospitals. A committee is looking into the possibility of telecasting operations to the Hotel Biltmore. After the exceedingly successful demonstration of the teaching value of television at the Clinical Congress in New York last year it is hoped that this medium can again be used.

In addition to meeting rooms in the Biltmore Hotel the Biltmore Theater and the spacious Philharmonic Auditorium across the street from the hotel will be used for the larger audiences. The capacity of the Philharmonic Auditorium is 2700 and that of the Biltmore Theater about 1700.

PRESIDENTIAL MEETING AND CONVOCATION

The opening evening session of the Clinical Congress will be devoted to the Presidential Meeting at which the officers-elect, consisting of Dr Dallas B Philmiste of Chicago as president, Dr

Howard A. Patterson of New York as first vice president, and Dr Carl H. McCaskey of Indianapolis as second vice president will be installed. Dr Arthur W. Allen of Boston, president and vice-chairman of the Board of Regents, will preside and will deliver the Presidential Address. The third Martin Memorial Lecture will be delivered by Dr Clarence Crafoord, Professor of Surgery University of Stockholm.

The annual Convocation will be held on the final evening, Friday. The formal initiation ceremonies and the presentation of the Fellowship Address by Dr L. A. Durbridge, President California Institute of Technology Pasadena, will constitute the program. Dr Durbridge's subject will be "The Physician Meets the Doctor."

SCIENTIFIC SESSIONS

The scientific sessions, to be held on Tuesday, Wednesday and Thursday evenings, will be devoted to subjects in general surgery carefully selected for their current interest, presented by authoritative speakers in their fields. On the same evenings separate scientific sessions will be arranged for specialists in ophthalmology and otorhinolaryngology. Every afternoon, from Monday through Thursday panel discussions will be held. These will be led by outstanding surgeons in each particular field. A symposium on fractures and other traumas and a symposium on cancer are planned for two afternoons.

OPHTHALMOLOGY AND OTORHINOLARYNGOLOGY

In addition to the evening sessions on ophthalmology and otorhinolaryngology which are scheduled for Tuesday Wednesday and Thursday evenings, there will be meetings for specialists in these fields on the same mornings. The sessions in otorhinolaryngology will follow those in ophthalmology so that surgeons who combine these specialties in their practice can attend both meetings. In planning all of the meetings in these fields, the suggestions of the members of the Advisory Council on Ophthalmology and of the Advisory Council on Otorhinolaryngology are followed in an effort to have the programs meet the ideas of the surgeons who practice these specialties.

FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

The Forum on Fundamental Surgical Problems, one of the most popular features of Clinical Congresses during the past few years, will be held on Tuesday Wednesday Thursday and Friday mornings, in two or three sections meeting concurrently. Brief reports of original clinical and experimental observations relating to the broad aspects of surgery and the surgical specialties will be presented under the general direction of Dr Owen H. Wangensteen, chairman of the committee, Forum on Fundamental Surgical Problems.

HOSPITAL CONFERENCES

The opening meeting of the twenty seventh Hospital Standardization Conference will constitute the first formal session of the Clinical Congress, and will be a General Assembly for both surgeons and hospital representatives. Dr Arthur W. Allen of Boston, president of the College, will preside.

The hospital conferences will continue on Monday afternoon, with sessions following on Tuesday Wednesday and Thursday mornings after noons, and evenings.

Hospital trustees, administrators, heads of the various hospital departments and their personnel, nursing groups, and many other persons directly or indirectly concerned about hospital progress are invited to participate in the discussions at the hospital conferences, at which leaders in the hospital field are the speakers and the moderators. The meetings will include formal sessions, panel discussions, round table conferences, symposia and forums.

A meeting which is always of great interest to hospital administrators and members of medical staffs in hospitals, as well as to surgeons, is the Symposium on Graduate Training in Surgery,

which is scheduled for Thursday afternoon after the annual meeting of Fellows.

MEDICAL MOTION PICTURES

An appreciated feature of the Clinical Congress will again be the showing of medical motion pictures each day. The latest available pictures on surgery and related subjects will be presented. Special showings will be arranged of medical motion pictures in the fields of ophthalmology and otorhinolaryngology. Both sound and silent films will be shown, all of which will have been approved by the Committee on Motion Pictures. Some of the newer medical motion pictures now under production will be shown.

TECHNICAL AND SCIENTIFIC EXHIBITION

The Technical and Scientific Exhibits will occupy the Ballroom foyer, the Renaissance Room, and the Galleria of the Biltmore Hotel according to present plans. Leading manufacturers of surgical instruments, x-ray apparatus, sterilizers, operating room lights, ligatures, dressings, hospital apparatus and supplies of all kinds and pharmaceuticals, and publishers of medical books will be represented.

ADVANCE REGISTRATION

Surgeons who wish to attend the Congress should register in advance. No registration fee will be charged Fellows whose dues are paid to December 31, 1947. For endorsed Junior and Senior Candidates the fee will be \$5.00. Non-Fellows attending as invited guests of the College will pay a fee of \$10.00. No fee will be required of initiates of the class of 1948.

HOTEL RESERVATIONS

It is desirable to make hotel reservations as early as possible because of the shortage of hotel rooms that prevails in Los Angeles as well as in other cities. In making these, communications should be addressed to the Los Angeles Convention and Visitors Bureau, care of the Los Angeles Chamber of Commerce, stating that you will be attending the Clinical Congress of the American College of Surgeons. All hotel reservations for the Clinical Congress are to clear through this Bureau. No correspondence should be sent directly to the hotels. A form for reservations was enclosed in the letter recently sent to Fellows. Choice of hotels may be designated. The hotels in Los Angeles require a deposit in advance.

There follows the list of member hotels, Convention and Visitors Bureau, Los Angeles Chamber of Commerce.

PARTICIPATION IN THE FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

OWEN H WANGENSTEEN M.D. F.A.C.S. Minneapolis, Minnesota

THE Board of Regents of the American College of Surgeons has again appointed a committee to invite and pass on the merits of the abstracts submitted and to select the papers for presentation in the Forum on Fundamental Surgical Problems at the next session of the Clinical Congress. In selecting papers for the Surgical Forum the committee is guided by originality of thought and interest suggested in the abstract submitted by the author. The Surgical Forum is concerned more with new work than with the dissemination of old information. Each speaker will be allowed 10 minutes for his presentation.

The final selection of papers for the Los Angeles meeting (October 18 to 22 1948) will be made by the committee in the near future. Anyone in

Chairman of Program Committee on Surgical Forum.

interested in participating in the program is invited to send before May 15 1948, the title of his presentation accompanied by an abstract of not more than 200 words, to

Forum on Fundamental Surgical Problems
American College of Surgeons
40 East Erie Street
Chicago 11 Illinois

The author may submit his paper for publication wherever he wishes.

COLLECTIVE REVIEW

- The Physiological Basis for Resuscitation of the Newborn DAVID M. LITTLE, Jr. A B M D
and RALPH M. TOVELL, M D M Sc. (Anes.) Hartford Connecticut 417

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

- Eye
Seborehic Blepharitis and Conjunctivitis. JOSEPH S. GOTS, PHILLIPS THORSON and MORRIS WATSMAN 439
Intraepithelial Epithelioma. BENJAMIN ESTERMAN, JOSEPH LAVAL, and CLARA OKRAJNETZ 439
A Consideration of Aniridia, with a Pedigree P. H. BEATTIE 439
Transplantation of the Vitreous. SAMUEL GARTNER and BRUNO S. PRIESTLEY 439
Visual Effects of Tridione. LOUISE L. SLOAN and ANITA P. GILGER 439
Disseminated Lupus Erythematosus. FREDERICK C. CORDES and SAMUEL D. Aiken 431

Ear

- The Nature of the Vestibular Stimulus. L. B. W. JOHNSON and J. J. GROSS 431
Healing of Experimental Labyrinthine Fistulas. Further Observations. J. R. LINDSAY 431
Labyrinthine Fenestration—The Present Position. C. A. HUTCHINSON 431
Stratigraphic Studies of Petromastoid Region. ALESSANDRO PIATTA 509

Nose and Sinuses

- Intranasal (Sphenopharyngeal) Encephalocele. Report of a Case with Intracranial Repair and a Review of the Subject. FRANK M. ANDERSON 431

Mouth

- Surgery of Cleft Palate. HECTOR MARINO 433
Survey of Pathologic Specimens from the Oral Regions Seen at the Army Institute of Pathology during World War II. JOSEPH L. BERNIER 433
Interosseous Wiring in the Treatment of Fractures of the Mandible. STUART GORDON 433
Intraseous Tumors of the Maxilla. H. BLUMENTHAL and H. BRUNSWER 434

Neck

- Syndrome of Avellis. A Review of the Literature and Report of a Case. SAMUEL L. FOX and G. BROOKS WEST JR. 434

- Propylthiouracil in the Treatment of Hyperthyroidism. E. PERRY McCULLAGH, RALPH E. HUBB, and ROBERT W. SCHNEIDER 435
Treatment of Graves' Disease with Radioactive Iodine. EARLE M. CHAPMAN 435
Two Cases of Tuberculosis of the Thyroid Gland. GIAMPAOLO COCCI 436
Cancer of the Thyroid Gland. Anatomical Types, Evolution and Results of Treatment in 35 Cases. ANTONIO LOTTEZ and ENRIQUE P. VIACAVA 436
Modern Trends in Surgery of the Thyroid Gland. FREDERICK A. BOTEE 436
The Treatment of Lymph Node Metastases from Intraoral Carcinomas with Special Regard to the Indications for Total Neck Dissection. ROLF WEYDE 437

SURGERY OF THE NERVOUS SYSTEM

- Brain and Its Coverings. Cranial Nerves
Cerebral Arteriography. BAUDILIO VILLANGUEVA 439
The Treatment of Focal Epilepsy by Cortical Excision. WILFRED PENNYFIELD and HARRY STEELMAN 439
Some Views on the Glioblastomas According to Scherer. J. DE BURACHER 440
The Role of Pituitary in the Causation of Diabetes Insipidus. GILBERT MORRAN 441
Cerebral Angiography. PHILIP J. HODGES, CHARLES R. PERRYMAN and RICHARD H. CHAMBERLAIN 509
Spinal Cord and Its Coverings
Streptomycin in the Treatment of Meningitis. Report of 27 Cases Treated at the Boston City Hospital. TOM FITZ PAINE, RODERICK MURRAY ALBERT O. SEEZLER and MAXWELL FINLAND 441
Peripheral Nerves
Regeneration in the Ulnar Median and Radial Nerves. EDWARD HAMLIN JR. and ARTHUR L. WATKINS 442

Miscellaneous

- The Carotid Sinus Syndrome. Its Surgical Treatment. RICHARD B. CATTELL and MARK L. WELCH 442

SURGERY OF THE THORAX

Chest Wall and Breast

- T U USUAL TUMORS of the Sternum THOMAS J KINKELLA, MARK WHITE, and R. W. KOCKY 443

Trachea, Lungs, and Pleura

- Three Cases of Bronchial Hamartoma, One Being an Endobronchial Polyp. O. A. ITOKI, R. I. LATI KHA, and A. J. MURRAY 443

- Recent Advances in Pulmonary Surgery CHARLES PHILAMORE BAILEY, FRANK TROFKA, JR., and LAURENCE H. RUBINSTEIN 443

- Pulmonary Infiltrations on Routine Chest Roentgenograms LEROY HYDE and BERNARD HYDE 509

- Carcinoma of the Bronchus with Especial Reference to Its Treatment by Radiotherapy L. M. SPORVOX 5

Heart and Pericardium

- Physiological Studies in Congenital Heart Disease. Measurements of the Circulation in 5 Selected Cases. L. D. VAN DAM, R. J. BING, and F. D. GRAY, JR. 444

- Wounds of the Heart 9 Cases. R. FERREIRA SANTOS, A. DIKO DE ALMEIDA, and F. C. SILVA TELLES 444

Esophagus and Mediastinum

- Esophageal Varices HERMAN J. MORRIS

- Clinical and Radiologic Features of Lymphatic Metastases in Carcinoma of the Thoracic Esophagus J. HORACIO REBOLLO 445

- The Differentiation of Mediastinal Tumor and Aneurysm by Angiocardiography MARCO L. SUMMAN 5

SURGERY OF THE ABDOMEN

Abdominal Wall and Peritoneum

- Massive Congenital Umbilical Hernia (Amniotic Hernia) JOSE M. JORAK 447

- The Importance of the Conformation of the Pelvis in the Genesis of Inguinal Hernia. CARLO PIAMA 447

- Streptomycin in Surgical Infections. Peritonitis. EDWIN J. FULAKI, SAM F. SEELBY, and CHARLES S. MATTHEWS 447

- Tumors of the Mesentery C. SIMONETTI 448

Gastrointestinal Tract

COLLECTIVE REVIEW

THE PHYSIOLOGICAL BASIS FOR RESUSCITATION OF THE NEWBORN

DAVID M LITTLE, Jr., A.B., M.D. and RALPH M TOVELL, M.D. M.Sc. (Athen.)
Hartford, Connecticut

A CENTURY now has passed since Sir James Simpson introduced both the use of the volatile anesthetic agents into obstetrics and the anesthesiologist into the confines of the delivery room. In the course of these hundred years, the anesthesiologist has come to join the obstetrician in being responsible not only for the safe and painless labor of the mother but also for the safe deliverance of her infant, including when necessary the resuscitation of that infant. This last responsibility is an eminently appropriate one the anesthesiologist being a specialist in the field of resuscitation. The fact that our fetal and neonatal mortality rates are improving but little, plus the fact that certain resuscitative procedures widespread in practice are based on extremely precarious physiological thinking suggested that it would be appropriate to review the literature on the subject of asphyxia neonatorum and its proper treatment.

THE INITIATION OF RESPIRATION IN THE NEWBORN

The age-old question of how breathing is initiated at birth remains one of science's greatest enigmas but some progress is being made toward the answer.

The time of onset of respiratory activity There is now evidence to indicate that respiratory movements are not necessarily initiated at or after birth they may begin in utero. Ahlfeld called attention to intrauterine respiratorylike move-

ments of the human fetus which he recorded graphically from the surface of the mother's abdomen and Snyder and Rosenfeld have succeeded in making motion pictures of such movements (214). Similar generalized rhythmic patterns which bear a close resemblance to respiratory movements have been observed prenatally in a variety of animals including the sheep (7, 8) the goat (6, 9) the rat (33) the rabbit (212) the guinea pig (213) the cat (213) the monkey (65) the chick (247, 253) and the duck (252).

A second line of evidence that the genesis of respiratory activity extends far back into embryonic life is furnished by observations of the respiratorylike behavior of human fetuses delivered early in their gestational lives. Erbham saw a 4 month old fetus open its mouth as though to breathe and Minkowski noted a deep inspiratory movement of the thorax in a fetus of the same age (158). Dragstedt observed a 4 month old fetus which executed rhythmic movements of the head and trunk as well as inspiratorylike movements resembling gasps (251) and Greene observed another fetus of that age in which 3 distinct respiratory movements were discerned (251).

Yet a third line of evidence of fetal respiratory activity is the demonstration of the entrance of amniotic fluid into the lungs before birth. It has long been known that amniotic fluid may become infected following premature rupture of the membranes (204) and it is now apparent that such infected fluid may enter the fetal lungs and cause intranatal pneumonia. Thus, Browne (20, 21)

Johnson and Meyer Warwick Odell and Plasz, Helwig Cruickshank Chase, Potter (175) Cameron and Farber and Sweet all reported finding either pneumonia or constituents of amniotic fluid in the lungs of stillborn infants. Snyder and Rosenfeld have performed experiments on animals to show that amniotic fluid enters the fetal lungs; they injected India ink into the amniotic sac of the rabbit and then demonstrated a flow of ink-stained amniotic fluid into the alveoli that was proportional to the rate of fetal respiratory activity (209 210 211 215 216 217) Shock has confirmed this work in the rat, but along with many other workers, he believed the phenomenon to occur only under conditions of intrauterine asphyxia. The entrance of amniotic fluid into the lungs before birth has also been shown by the technique of obtaining x rays of the fetus following the injection of thorotrast into the amniotic sac. Windle Becker Barth and Schulz (249) showed that thorotrast introduced about the head of the guinea pig fetus may be aspirated and demonstrated by means of x-rays. Ehrhardt and Reifferscheid and Schmiemann are reported to have injected thorotrast into the amniotic sacs of human patients before therapeutic abortion and subsequently to have found the radiopaque substance in the fetal gastrointestinal tract and lungs. Davis and Potter (49) injected thorium into the amniotic sacs of 16 women in the first half of pregnancy before therapeutic hysterotomy and demonstrated thorotrast in the gastrointestinal tracts and lungs of all the fetuses microscopically. They repeated these experiments in 10 women in the second half of pregnancy before cesarean section, and radiographic studies of the infants following delivery showed thorotrast in the lungs in half of them.

The mechanism of onset of respiratory activity. A number of theories have been propounded to explain the mechanism of onset of fetal respiratory activity and the initiation of the first inspiratory gasp of the newborn. An early one was Preyer's mechanical theory which attributed the initiation of respiration at birth to physical factors and the reflex stimulation of the respiratory center by the trauma of labor. This view is refuted empirically by the failure of rough palpation manual version and the application of forceps to initiate breathing if the fetus placental circulation remains intact (73).

As the facts concerning the chemi- respiration became known, various theories were postulated. It is a well-known fact that clamping the umbilical cord the first inspiratory gasp (24, 28)

hypothesized that the onset of respiration occurred because of insufficient oxygen, an excess of carbon dioxide, or a change in the pH of the blood. Windle Barker and their coworkers do not believe that fetal respiratory activity occurs under normal physiological conditions, and they believe that such activity as well as the initiation of respiration after birth is dependent upon asphyxia, anoxemia, and an increasing tension of carbon dioxide (6 8, 12 239 244, 245, 247 248, 249, 251 252 253). A number of other workers support these views (25, 80 97 122 173 201 256). Henderson and his followers have stressed that it is the carbon dioxide tension of the blood that is the excitatory stimulus of respirations (1 102, 104, 105 108 238, 243). Coryllos (34) stated that the true respiratory hormone is the pH of the blood, and that the important factor is the carbonic acid-bicarbonate ratio rather than the absolute value of the carbon dioxide tension.

Snyder and Rosenfeld and Eastman have advanced what may be termed the biological theory of the initiation of respiratory activity. They have shown that anoxemia and an increased tension of carbon dioxide may actually inhibit fetal respiratory efforts (212, 213 188) and that the onset of respirations at birth cannot be correlated with the tension of carbon dioxide in the infant's blood (69). Snyder and Rosenfeld have further demonstrated that the tidal flow of amniotic fluid into the lungs results in alveolar distention (211). They have postulated that the fetus is not normally apneic in utero; that postnatal breathing is merely a continuation of intrauterine respiratory activity and that asphyxia neonatorum represents a suppression of this activity (187 189). Davis and Potter reached the similar conclusion that the respiratory activity of the human fetus *in utero* is related to that after delivery; the major change in respiration at birth involving the substitution of air for amniotic fluid as a medium of exchange (249).

Apparently intranatal respiratory activity definitely does occur but whether it occurs as a normal function related to postnatal respiration, or merely as a manifestation of intrauterine asphyxia, cannot be ascertained on the evidence so far presented.

neonatorum should be reserved for those infants exhibiting the true syndrome of asphyxia

Classification. Although numerous classifications of the stages of asphyxia neonatorum have been devised, they all share a common basis: they describe varying degrees of lack of oxygen. Thus, one group of workers speaks of asphyxia livida and "asphyxia pallida" (151 185 203) a second group of initial apnea 'initial dyspnea, terminal apnea, and arrest of the heart (34 35 223) and a third group of mild moderate, and severe asphyxia (83 136 144, 193) Flagg's classification describes the degree of lack of oxygen in terms of physical findings—the stage of depression, the stage of spasticity and the stage of flaccidity—a classification of immediate importance to those faced with the necessity of resuscitating the asphyxiated newborn (86)

In the depressed stage the baby does not breathe well. There is a tendency to recurring cyanosis or duskiess. The infant is depressed but capable of being aroused the respiratory center circulates, muscular tonus, and reflexes are all depressed from anoxemia but are easily stimulated to normal activity. In the spastic stage respirations are irregular gasping or shallow and occur at long intervals. There is marked cyanosis of the mucous membranes. There is reflex reaction to aspiration within the pharynx and an active glottic reflex is present. Froth or fluid appears in the mouth and pharynx. In the flaccid stage, respirations occur either at long intervals or cannot be demonstrated. There may be either cyanosis or pallor. There is complete flaccidity of all the musculature the jaw is completely relaxed the glottic structures are collapsed and there is no resistance on exposure of the pharynx. Fluid is found in the hypopharynx. All reflexes are in abeyance. Cardiac pulsation may or may not be demonstrable at the apex. The circulation is failing (86)

Etiology. The list of the etiological factors of asphyxia neonatorum is a long one, and the complete syndrome is usually the result of a combination of several of these factors, rather than any given single factor in itself

It has been found that the age of the mother is of no importance until the age of 40 years is reached but that thereafter the incidence of asphyxia increases markedly (143 194) The parity of the mother is a factor primiparas giving birth to asphyxiated babies more frequently than multiparas (30) until after the eighth baby when the incidence of asphyxia increases with parity (142) The health of the mother is also a factor cardiac

disease cardiac failure, anemia pulmonary disease, infectious diseases of the genitourinary or gastrointestinal tracts, metabolic diseases such as diabetes or thyrotoxicosis, deficiency diseases, hyaline pertussive states, and the toxemias of pregnancy all markedly increase the incidence of asphyxia (11 27 142 170, 193)

The viability of the germ plasma and the development of fetal disease or congenital anomalies may be of importance. Congenital debility congenital defects such as malformations of the respiratory and circulatory systems, diaphragmatic hernia, hypoplasia of the mandible, abnormal mobility of the tongue and congenital diseases such as syphilis and erythroblastosis, have all been cited as factors tending to induce asphyxia (13 27 67 146 170)

There is little doubt that the immaturity of the infant plays an important part in the production of asphyxia neonatorum (13 27 30 128 170 176 193 194, 229) Lund considered that immaturity constituted the most important single factor in the production of asphyxia neonatorum (142) as did Sege. However Eastman states that while prematurity is a common cause of death it is not, *per se* a prominent cause of asphyxia neonatorum (67) Some credence is lent this statement by the experimental work of Glass and Snyder who found an increased tolerance to anoxia in rabbits, dogs, and guinea pigs born prematurely

The presentation and position of the fetus in utero (breech transverse, and occiput posterior presentations and positions) are factors which increase the incidence of asphyxia (27, 142) The induction of labor with drugs, particularly quinine and pituitrin, is said to be a factor in producing asphyxia in some instances (11 52 142) The duration and type of labor is of importance long dry labor or the long difficult labor associated with dystocia and cephalopelvic disproportion markedly increases the tendency toward asphyxia (11 27 142 146 170) as does the pernicious practice of prolonging labor by mechanical force to prevent the delivery of the infant merely for the sake of convenience (52) Russ and Strong thought that prolonged labor was the outstanding cause of fetal asphyxia (194)

The complications of labor are important factors. These include anoxemia of placental origin such as gross infarction low insertion placenta previa, and premature separation of the placenta anoxemia originating in the cord due to placental shortness, knotting or kinking the cord about the neck, compression or torsion or a velamentous rupture and anoxemia of uterine origin such as tetany a contraction ring or hemorrhage (11 27

Johnson and Meyer Warwick Odell and Plass, Helwig Cruickshank Chase Potter (175) Cameron and Farber and Sweet all reported finding either pneumonia or constituents of amniotic fluid in the lungs of stillborn infants. Snyder and Rosenfeld have performed experiments on animals to show that amniotic fluid enters the fetal lungs: they injected India ink into the amniotic sac of the rabbit and then demonstrated a flow of ink-stained amniotic fluid into the alveoli that was proportional to the rate of fetal respiratory activity (209 210 211 215 216 217). Shock has confirmed this work in the rat but along with many other workers, he believed the phenomenon to occur only under conditions of intrauterine asphyxia. The entrance of amniotic fluid into the lungs before birth has also been shown by the technique of obtaining x rays of the fetus following the injection of thorotrast into the amniotic sac. Windle Becker Barth and Scholz (249) showed that thorotrast introduced about the head of the guinea pig fetus may be aspirated and demonstrated by means of x rays. Ehrhardt and Reifferscheid and Schmiemann are reported to have injected thorotrast into the amniotic sacs of human patients before therapeutic abortion and subsequently to have found the radiopaque substance in the fetal gastrointestinal tract and lungs. Davis and Potter (49) injected thorium into the amniotic sacs of 16 women in the first half of pregnancy before therapeutic hysterotomy and demonstrated thorotrast in the gastrointestinal tracts and lungs of all the fetuses microscopically. They repeated these experiments in 10 women in the second half of pregnancy before cesarean section and radiographic studies of the infants following delivery showed thorotrast in the lungs in half of them.

The mechanism of onset of respiratory activity. A number of theories have been propounded to explain the mechanism of onset of fetal respiratory activity and the initiation of the first inspiratory gasp of the newborn. An early one was Preyer's mechanical theory which attributed the initiation of respiration at birth to physical factors and the reflex stimulation of the respiratory center by the trauma of labor. This view is refuted empirically by the failure of rough palpation, manual version and the application of forceps to institute breathing if the fetus placental circulation remains intact (73).

As the facts concerning the chemical control of respiration became known, various chemical theories were postulated. It is a well known fact that clamping the umbilical cord often initiates the first inspiratory gasp (24, 28) and it has been

hypothesized that the onset of respiration occurred because of insufficient oxygen, an excess of carbon dioxide or a change in the pH of the blood. Windle Barker and their coworkers do not believe that fetal respiratory activity occurs under normal physiological conditions, and they believe that such activity as well as the initiation of respiration after birth, is dependent upon asphyxia, anoxemia, and an increasing tension of carbon dioxide (6 8 12 239 244, 245 247 248, 249, 251, 252 253). A number of other workers support these views (25 80 97 122 173 201 256). Henderson and his followers have stressed that it is the carbon dioxide tension of the blood that is the excitatory stimulus of respirations (1 202, 204, 205, 208 238 243). Coryllos (34) stated that the true respiratory hormone is the pH of the blood, and that the important factor is the carbonic acid-bicarbonate ratio rather than the absolute value of the carbon dioxide tension.

Snyder and Rosenfeld, and Eastman, have advanced what may be termed the biological theory of the initiation of respiratory activity. They have shown that anoxemia and an increased tension of carbon dioxide may actually inhibit fetal respiratory efforts (212 213 283) and that the onset of respirations at birth cannot be correlated with the tension of carbon dioxide in the fetal blood (69). Snyder and Rosenfeld have further demonstrated that the tidal flow of amniotic fluid into the lungs results in alveolar distention (211). They have postulated that the fetus is normally apneic in utero; that postnatal breathing is merely a continuation of intrauterine respiratory activity and that asphyxia neonatorum represents a suppression of this activity (187 189). Davis and Potter reached the similar conclusion that the respiratory activity of the human fetus in utero is related to that after delivery; the major change in respiration at birth involving the substitution of air for amniotic fluid as a medium of exchange (249).

Apparently intrauterine respiratory activity definitely does occur but whether it occurs as a normal function related to postnatal respiration, or merely as a manifestation of intrauterine asphyxia, cannot be ascertained on the evidence so far presented.

ASPHYXIA NEONATORUM

Asphyxia means, literally, the absence of pollution. In common medical parlance, however, asphyxia neonatorum has come to mean the failure of the newborn to breathe at birth. Apnea neonatorum would appear to be better terminology to employ in such instances, and the term "asphyxia

128, 142 146 177, 185 193 194 229) The type of delivery also influences the incidence of asphyxia. Version and extraction high forceps, breech extraction, mid-forceps, cesarean section and low forceps delivery without episiotomy are associated, in the order given with a frequency of asphyxia which is higher than that with spontaneous delivery (27 30, 52 128, 142 193 194).

The analgesic drugs often play a major role in the production of asphyxia neonatorum. Irving reported that if neither analgesics nor anesthetics were given to the mother, only 1.9 per cent of the infants failed to breathe immediately at delivery whereas from 30 to 60 per cent of the infants born to narcotized mothers were asphyctic. Experimental work has shown that the intrauterine respiratory activity of the fetus is inhibited by the administration of pentobarbital sodium amylal morphine paraldehyde, or chloral hydrate to the mother (18 187 189). Morphine in particular has been condemned (22 129 134, 174 195) especially when used in large doses within 1 to 6 hours of delivery and in conjunction with other methods of analgesia and anesthesia (27 29 112 145 202 219). The barbiturates, when first introduced were regarded as the answer to the problem of obstetrical analgesia (19, 54, 139, 186) but it has become apparent that they too contribute to fetal respiratory depression (16 22 29, 112 120, 134, 195). Demerol, scopolamine, paraldehyde, heroin and pantopon all increase the frequency of asphyxia in the infant (92 120 129 142 190). The pain-relieving drug that does not increase the incidence of asphyxia neonatorum has not yet been found.

All the anesthetic agents and methods play a part in the production of asphyxia neonatorum with the possible exception of local infiltration with or without peripheral nerve block (26 36 52 141). Spinal continuous spinal, caudal, and continuous caudal anesthetics are almost ideal from the viewpoint of prevention of asphyxia in the fetus, except when these methods are complicated by a decrease in the blood pressure or by manifestations of idiosyncrasy (36 96 196 218 227). All general anesthetics used to the point of maternal anesthesia decrease the respiratory response of the newborn (98). Nitrous oxide produces marked anoxemia of both the maternal and fetal bloods (205) and it is exceedingly dangerous to the fetus in concentrations greater than 85 per cent (66). Cyclopropane increases the oxygenation of the maternal blood, but it is claimed to oxygenate the fetal blood poorly (205) and, when used in concentrations sufficient for operative delivery increases the incidence of asphyxia (144).

Ether depresses intrauterine fetal respiratory activity (18) decreases fetal oxygenation (66), and narcotizes the infant (96, 208). In short, anesthesia, like analgesia, is produced for the mother with the hazard of asphyxiating her child.

Finally and frequently most importantly the skill and experience of both the obstetrician and anesthetist may influence the incidence of asphyxia neonatorum (27).

Chemistry Eastman's classical studies of the chemical changes occurring in the blood of the asphyxiated newborn (63 64, 68, 69, 70, 71), confirmed by others (95, 123 132 205, 243) indicate that asphyxia neonatorum is a chemical phenomenon associated with a decrease in the concentration of oxygen, an increased tension of carbon dioxide, a marked increase in lactic acid, and a decrease in pH of the fetal blood. In the normal newborn, the arterial oxygen capacity is 15 ml (20.8 volume per cent) the arterial oxygen content low (10.5 volume per cent) and the arterial oxygen saturation therefore, low (50.5 per cent). In asphyxia neonatorum, the oxygen content of the blood may fall to less than 1 volume per cent with a fatal outcome and the oxygen saturation may be only between 0.5 and 4.0 per cent. The lactic acid content of the blood of the normal newborn is 35 milligrams per 100 cubic centimeters, but under conditions of asphyxia this may rise to from 85 to 100 milligrams per 100 cubic centimeters, which indicates a definite endogenous production. The carbon dioxide tension of the blood, which is normally 32 millimeters of mercury in the newborn, rises to twice that value in asphyxia neonatorum, and at the same time the carbon dioxide content falls to low levels as a result of its displacement from base by the large amount of lactic acid present in the blood. The pH of the blood, normally 7.35 in the newborn falls to 7.05 the lower level compatible with life, and may even fall to below 7.00 with a fatality ensuing.

Pathology Although it has been demonstrated experimentally that intrauterine respiratory activity and the aspiration of amniotic fluid produces some dilatation of the pulmonary alveoli under certain circumstances (216) clinically the fundamental pathological lesion of asphyxia neonatorum is the complete atelectasis of the lungs. The lung is airless and is not crepitant, the alveoli are collapsed and the parenchyma is fleshy and dark colored. The lung is a compact, solid viscus which completely fills the thorax, for negative intrapleural pressure has not been developed (14). Even after respiration begins, partial atelectasis may persist for long periods (62 105). Wason has shown roentgenographically that expansion of the

between the carbon dioxide tension and the onset of spontaneous respirations in the newborn (60) and others have confirmed the fact that the use of carbon dioxide in conjunction with the administration of oxygen will not initiate respirations more readily than, and indeed not even as readily as oxygen alone (1 13 44 64 68 98 13 169 170 212 213). Furthermore it has been pointed out that carbon dioxide in concentrations above 10 per cent exhibits its anesthetic properties and becomes actually depressant to respirations (15 55 119). In fact, under conditions of anoxia the respiratory center undergoes a reversal as far as its response to carbon dioxide is concerned and eventually even low concentrations of that agent may be depressant. Finally with the occurrence of what Schmidt terms the revolution in respiratory physiology it has come to be realized that when the respiratory center is depressed the impulses for the stimulation of respiration arise from the aortic and carotid bodies (which are very sensitive to anoxia but relatively insensitive to increased carbon dioxide tensions) as well as from the respiratory tract joints skin and subcutaneous tissues (31 32 67 107 198).

Methods of artificial respiration. When the newborn remains apneic following the establishment of an unobstructed airway the administration of oxygen through that airway becomes a problem of artificial respiration. Such artificial respiration must exert sufficient force to overcome the resistance of the atelectatic lungs to expansion. Wilson and Farber found that this resistance amounted to from 25 to 30 centimeters of water in the lungs of premature infants at autopsy (206). Smith found the resistance to be from 20 to 30 centimeters of water in the lungs of normal human infants at birth (206). Gruenwald who believes that surface tension is the highest single factor of resistance to expansion in the lungs of the newborn found that an average pressure of 18 centimeters of water was required to expand the lungs of the newborn and stillborn when air was employed but that only 9 centimeters of pressure were required when water was employed to expand such lungs. Wilson Torrey and Johnson (243) concluded that pressures of 24.4 centimeters of water were not great enough to expand the lungs of stillborn infants but were great enough to cause gross pulmonary damage. Others have warned that even low pressures may cause alveolar rupture or vascular damage in the lung. Murphy and Bauer warned that in the Drinker type of respirator the negative pressure must not exceed 15 centimeters of water (161). Kreiselman (131) advised a maximum of 21.6 centimeters of

water positive pressure applied over the face. Flagg advocated 5.4 centimeters of water positive pressure (82) and Henderson allowed 5 millimeters of mercury positive pressure (107). The Drinker infant resuscitator provides a negative pressure of 10 centimeters of water (163) the Kreiselman inhalator a positive pressure of up to 16 millimeters of mercury (130) and the Ericson and Johnson resuscitator a positive pressure of 13 millimeters of mercury and a negative pressure of 9 millimeters of mercury (40). It is an enigma that the mechanical resuscitators for use in the treatment of asphyxia neonatorum provide pressures that are far lower than those estimated to be required to overcome the resistance of the lungs of the apneic newborn and yet that those same pressures may produce gross pulmonary damage in such lungs. At least a partial explanation lies in the fact that pulmonary damage may be as much dependent upon the suddenness with which such pressures are applied as upon the pressures themselves.

Artificial respiration may consist of the intermittent exaggeration of negative intrapleural pressure the intermittent increase of the pressure in the alveolar spaces, or the alternating increase and decrease of the pressure in the alveolar spaces.

Manual artificial respiration consisting of the intermittent compression of the lower thoracic cage and thus a method depending on the exaggeration of negative intrapleural pressure is often advocated (2 8 154 166 185 203). This resuscitative procedure may be combined with the use of oxygen supplied by machines such as the Henderson and Haggard inhalator (103 115) or by a simple mask and bag. Once spontaneous respirations have been initiated it may be possible to aid and assist them in this way. However there is no physiological basis for the use of this procedure in the face of persistent apnea for it is not possible to exaggerate a negative intrapleural pressure that has not yet developed. It is not possible to force air out of completely atelectatic lungs. It is not possible to accomplish an inspiratory act by the elastic recoil of an atonic thoracic cage (1, 2 52, 10 132 136 153 43).

The rocking method of artificial respiration developed by Eve (7 8 70 15) has been used in the resuscitation of the asphyxiated newborn (8, 157). This method also consists of the development of an increased negative intrapleural pressure but it is doubtful whether in most cases the weight of the abdominal viscera can produce sufficient negative intrapleural pressure to overcome the atelectasis of the apneic newborn (243). The procedure has the added theoretical disadvantage

delenburg position (52 67) is now considered the optimal position for the asphyxiated newborn.

If the infant is in the stage of flaccidity with collapsed glottic structures and absent glottic reflex, it is mandatory to intubate the trachea not only for the purpose of aspiration but also in order to maintain an airway through which the lungs may be insufflated with oxygen (3 4 17 52 83 84, 93 118 132 136 140 146 149 152 202 229 230). Ardent advocates of this operation believe that it is easily performed after but little training (82 152 243 254) by either a 'blind technique' (51 149) or with specially designed infant laryngoscopes (3 17 83 84 85, 86, 137 146 218 228 232). The more conservative writers warn that it is a maneuver that requires considerable skill, and that the novice may find it both slow and difficult to accomplish (166) without trauma to the larynx (82 138 220, 229).

The use of external stimulation. Few workers still advocate the Schultze Giant Swing (185) the performance of a gentle dorsal slit (152) hot and cold tubbing, sprinkling the skin with ether, jack-knifing the infant, dilating the anal sphincter, vigorous spanking, pummeling and other archaic methods of manhandling the asphyxiated infant in the hope of stimulating the respiratory center with afferent impulses. Gentleness is now stressed and the dangers of increasing shock, causing visceral lacerations, and inviting cerebral hemorrhage are emphasized (1 34, 52, 102 132 137 154 166 196, 202 230). Nevertheless, the anoxic respiratory center may be stimulated by afferent impulses from the skin, subcutaneous tissues and joints (31 32 61 197 198) and gentle cutaneous friction and passive movements of the extremities, after the establishment of an unobstructed airway, may effect the initiation of respiration in the mildly depressed newborn without the necessity of recourse to other procedures (112 193 118 218 228).

The administration of oxygen. If the newborn does not respond immediately to such measures, oxygen must be administered. Eastman (63) as noted before, has demonstrated that the oxygen content of the fetal blood is reduced to extremely low levels. He believes that although the changes in lactic acid content, pH and carbon dioxide tension are marked (64, 68 69, 70, 71) these changes are secondary the primary chemical change in asphyxia neonatorum being the extreme reduction in the oxygen content of the infant's blood. He has summarized his firm convictions by stating, "There seems to be only one urgent indication in the treatment of asphyxia neonatorum, and that is to introduce oxygen into the cir-

culating blood of the infant." There is unanimous agreement among almost all other authorities that the administration of oxygen constitutes one of the essential procedures in the resuscitation of the asphyxiated newborn.

Concerning the questions of methods by means of which oxygen should be introduced into the circulating blood, and of whether or not it should be used in conjunction with the administration of carbon dioxide there is considerably less agreement.

The administration of carbon dioxide. Selkirk has one man championed a therapeutic measure as strenuously as Yandell Henderson did the use of carbon dioxide for the treatment of depressed respiration and the asphyxias, including asphyxia neonatorum (101 110, 111 112, 117). He stated that carbon dioxide was the physiological respiratory stimulant (99 102 109, 114, 116) in large measure basing his conclusions on the successful use of that agent in the resuscitation of victims of carbon monoxide poisoning (103, 115) and he hypothesized that carbon dioxide produced the muscular tonus he believed necessary for the onset of respirations at birth (108). He justified the administration of carbon dioxide to the asphyxiated newborn, in the face of an already high carbon dioxide tension, on the basis that the respiratory center was so depressed that it was sensitive only to extremely high concentrations of that agent (104 105). He did not fear to induce acidosis by the administration of carbon dioxide in such circumstances, for he did not regard what others called the 'acidotic' condition of the asphyxiated newborn as true 'acid poisoning' (106). A large number of workers have agreed with Henderson that the administration of carbon dioxide is essential in the resuscitation of the asphyxiated newborn and that oxygen alone is merely a food-stuff, not a respiratory stimulant (10, 52, 72, 73, 83 84, 85, 128 136 185, 202). Henderson and supporters of his thesis believe that 93 per cent oxygen with 7 per cent carbon dioxide is the ideal mixture of gases for routine use in resuscitation (3 17 34, 35 137 146, 149, 152, 154, 155, 219, 229). In the presence of profound asphyxia, and in the hands of experienced workers, however, it has been advocated in the past that up to 30 per cent carbon dioxide be employed (159, 151 103, 243).

Carbon dioxide may be of use as a stimulant when respirations become depressed during the first days of life (46 118 218) but there are now a number of reasons for believing that its use cannot be justified in the treatment of asphyxia neonatorum. Eastman could find no correlation

The use of stimulatory drugs Epinephrine given intracardially has been advocated for cardiac failure occurring in asphyxia neonatorum (52 149, 156 166) and some remarkable recoveries have been attributed to its use (235). It is now recognized however that epinephrine frequently precipitates ventricular fibrillation (56 140) and its use is therefore contraindicated.

Alpha lobeline has been reported to be of immense value for initiating respirations in the newborn by Wilson and his coworkers (241 242 243) as well as others (52 137 193 203). Careful studies of the drug however have revealed that its respiratory stimulative properties are variable in occurrence temporary in duration associated with cardiac depressant properties, and appear only in doses that are at convulsant levels (37 45 85 118 126 147 152 167 236).

Pituitrin, camphor coramine, picrotoxin, me trazol caffeine, and strychnine have all been used as stimulants in the treatment of asphyxia neonatorum (149 153 154 155 166) but they are capable of doing more harm than good (1 11 56 70, 132 135, 147 218 230). These so-called stimulatory drugs are not selective stimulators of the respiratory and vasomotor centers rather they stimulate those centers in the course of their action as generalized cerebral stimulators (91). Davis and his coworkers (48) found that the oxygen tension of the cat's brain fell to low levels during convulsions produced by such drugs. Since it had been shown previously that there was no change in the cerebral circulation before or during an induced seizure (88 89, 121 172) they interpreted their work as indicating that this relative anoxia was caused by increased cerebral metabolism. Schmidt and his coworkers (199) confirmed this work in the monkey they found that the cerebral oxygen uptake invariably changed in the same direction as the cerebral functional activity and that the highest levels of cerebral oxygen uptake were produced by convulsant drugs. The use of such drugs was often followed by a more severe depression than that which it was intended to overcome and recovery from the effects of cerebral depressants occurred distinctly more rapidly when no analeptic was given. These studies led Schmidt to question the use of stimulatory drugs in the treatment of cerebral anoxia, since they raise the demand for oxygen beyond the available supply (198). He even suggests the cautious use of cerebral depressants in certain situations of cerebral anoxia. Kety's method for the quantitative determination of cerebral blood flow and metabolism in man will undoubtedly be applied to this problem and in time we may

even have measurements of the oxygen consumption of the asphyxiated newborn before and after the use of stimulatory drugs. Until that time however it would appear from the experimental evidence that the use of these drugs is of questionable value, and may even be definitely harmful.

The enzymatic compound cytochrome C has been shown to be useful in combating certain types of anoxia in man (180) but as yet it has had an insufficient trial as a therapeutic agent in the problem of asphyxia neonatorum.

SUMMARY

1. Intrauterine respiratory activity of the fetus does occur whether this occurs normally as the physiological forerunner of postnatal respiration, or only under abnormal conditions, has not yet been determined.

2. Asphyxia neonatorum is a generic term used to describe lack of oxygen of varying severity occurring in the newborn infant. The etiological factors of this syndrome include the age of the mother the parity of the mother the health of the mother the viability of the germ plasma the immaturity of the infant, the presentation and position of the fetus the medical induction of labor the duration and type of labor the complications of labor the type of delivery the analgesic drugs employed, and the anesthetic agents and methods employed. Chemically the syndrome is characterized by a decrease in content of oxygen in the fetal blood a secondary increase in the tension of carbon dioxide an increase in the content of lactic acid, and a decrease in the pH of the fetal blood. The primary pathological lesion of asphyxia neonatorum is atelectasis of the lungs secondary pathological lesions result from anoxia. Permanent irreparable damage of the central nervous system may result from the anoxia of asphyxia neonatorum.

3. The establishment and maintenance of an airway is the first requirement in resuscitating the asphyxiated newborn. This may be followed by extremely gentle external stimulation. Oxygen must then be administered, by a form of artificial respiration, if necessary. Carbon dioxide should not be used in conjunction with the administration of oxygen. Warmth should be maintained throughout the resuscitative period and thereafter. Stimulatory drugs may do more harm than good and should not be used.

tage of requiring periods of steep Trendelenburg position, which may initiate or aggravate the complication of intracranial hemorrhage.

Respirators of the Drinker type (58 60) adapted in size to infants (38 53 59, 107) induce a negative intrapleural pressure by subjecting the external thoracic cage to a negative pressure equal to 10 centimeters of water. Those who advocate their use point out that while such respirators may not actually initiate respirations, they will maintain oxygenation and life in the most physiological manner yet devised until spontaneous respirations occur (34, 42 84 110 118 155 160, 162 164, 165 181). However studies of the lungs of infants so treated but who have come to autopsy have shown that very little pulmonary aeration has occurred with the use of such low pressures (17 94, 136, 243) and yet that, at times, gross pulmonary damage has been done (50). It has also been emphasized that it is extremely difficult to regulate the rate and rhythm of the respirator to the irregular respirations of the asphyxiated infant when respiratory efforts finally do begin; thus, they may become completely inhibited altogether (152).

Mouth-to-mouth insufflation is the simplest method of intermittently increasing the pressure in the alveolar spaces, and this method may also be used alternately to increase and decrease that pressure. The mouth-to-mouth method has been warmly recommended as an immediately available way of supplying at least some oxygen (5 34, 35 55 73 82 128 149 154, 155 228, 229 237) but even its advocates warn that there is a great danger of creating an excessive intrapleural pressure and thus causing fatal emphysema and pneumothorax (12 34, 50, 73 75 118 137 152 203 218 243). Unless intratracheal intubation has been performed, there is also the danger of overdistending the stomach and rupturing it (17 243) although this danger may be mitigated by the use of gentle pressure on the epigastrium. Finally there is the danger of infection, both to the infant and in diseases such as congenital syphilis, to the operator (12 185 243).

Another method of intermittently increasing the pressure in the alveolar spaces is by the use of a face mask and an inhalator such as the Kreiselman resuscitator (127 130 131 161 228 232). This machine is designed to supply intermittent flows of oxygen under positive pressure at a maximum value that can be controlled by the operator although this value is usually never above 15 or 16 millimeters of mercury. Pulmonary damage is unlikely although it may occur at such pressures but pulmonary expansion is also unlikely at such

pressures, although it too may occur (17 203). As with other methods employing positive pressure, there is the danger of distending the stomach.

Resuscitators that provide alternate increase and decrease of the pressure in the alveolar spaces such as the Erickson and Johnson resuscitator (34 40 171) have been both recommended (13, 114 148, 191 192, 193 218, 231) and condemned (5, 136 169, 230). The objections to the "suck-and-blow" resuscitators are the dangers of pulmonary damage from both positive and negative pressures (110 113 152) the danger of overinflating the stomach (152) the fact that such machines frequently become mechanically defective at the critical moment (84 100) and the fact that such machines may adapt to slight obstructions in the airway rather than to the volume of the lungs of the newborn (117 152). However a number of other workers employing these machines have been able to demonstrate no injurious effects on the lungs (148 152 181 191, 231). The experiments of Thompson and Birnbaum, wherein they effected the resuscitation of asphyxiated dogs by using 100 per cent nitrogen and other physiologically inert gases, with this so-called "suck-and-blow" method, are worthy of comment (14, 15 35 221 222 223, 224). By the use of nitrogen in a "suck-and-blow" resuscitator they could reverse a larger percentage of asphyxiated animals than by the use of oxygen with manual artificial respiration (221 223). It is the belief of Thompson and Birnbaum that deflation initiates powerful stimulatory impulses for respiration which travel over the vagus (15 35, 222) and which can not be elicited by inflation alone. Reicher has confirmed their work. More recently Thompson and his co-workers have injected radioactive sodium into the femoral veins of asphyxiated dogs and have demonstrated a greater circulatory movement with "suck-and-blow" resuscitation than with other methods of artificial respiration (225). They repeated this work, using oxygen as the tracer (226), but the findings were still at variance with those of other workers (57 231).

The maintenance of warmth. The majority of workers are agreed that in asphyxia neonatorum the warmth of the body should be maintained by blankets, tub or incubator. The recent concept that heat, by increasing the metabolism, may increase shock and therefore be contraindicated in the presence of shock has not yet been applied to the problem of the asphyxiated newborn. It is interesting to note in this connection however that a decrease in temperature was shown experimentally to be an important factor in aiding the survival of anoxic newborn puppies and rats (81).

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

EYE

Seborrheic Blepharitis and Conjunctivitis. JOSEPH S. GOTZ, PHILLIPS THYNGSTON and MORRIS WATSMAN. *Am. J. Ophth.* 1947 30 1485

The authors report their observations on Pityrosporum ovale in seborrheic blepharitis and conjunctivitis. Except when secondarily infected seborrheic dermatitis of the eyelids is a mild almost symptomless disease. However some cases are associated with acute conjunctivitis and keratitis. Although pityrosporum ovale is the only constant bacteriologic finding in the disease its rôle in this condition is unsettled because seborrheic dermatitis does not occur in animals and animal inoculations fail to reproduce the disease. Moreover the few recorded human inoculations with this unclassified yeastlike organism have been inconclusive, so that it is difficult to determine whether the organism occurs as a saprophytic or as an etiologic agent. It was found in scrapings from 100 per cent of 143 cases of clinically recognizable seborrheic dermatitis of the eyebrows and eyelids—in moderate numbers in mild cases and in enormous numbers in severe cases. Skin tests with extract of Pityrosporum ovale in 16 individuals without gross seborrheic blepharitis or dermatitis of the scalp resulted in questionable or negative reactions but in 5 of 46 individuals with seborrheic dermatitis of the eyelids the resultant skin reactions were significant. Three of these 5 patients developed severe lesions of the conjunctiva and cornea.

It is concluded that although no conclusive evidence was found that Pityrosporum ovale was pathogenic for the eye and its adnexa, its etiologic relationship is suggested by the following findings: the constant presence of the organism in the lesions; the relationship between the number of organisms and the severity of the disease; the relative absence of the organism in clinically normal eyes; the inability of the organism to grow on any but complex culture media (saprophytes grow on simple media) and the sensitization to the organism revealed by intra-dermal skin tests. JOSEPH S. GOTZ, PHILLIPS THYNGSTON and MORRIS WATSMAN. *Am. J. Ophth.* 1947 30 1485

Intraepithelial Epithelioma. BENJAMIN ESTERMAN, JOSEPH LAYAL, and CLARA OKRAJNYL. *Am. J. Ophth.* 1947 30 1537

The authors report a case of intraepithelial epithelioma of the cornea and conjunctiva (Bowen's disease). Only 7 cases have been reported in the literature.

In all cases complete surgical excision was always considered the treatment of choice (although the difficulties of complete excision were mentioned in

1 case). Radiotherapy has not been advocated and some pathologists are even of the opinion that it is contraindicated. In 1 case treated by radiation there was no recurrence during the remaining 4 years of the patient's life.

In the present case report the condition occurred in the right eye of a woman 63 years of age. The vision which was 10/200 could not be improved. The tumor situated at the lower nasal quadrant of the limbus presented a pinkish gray granular appearance about 5 mm. in diameter. The mass was slightly elevated and had the texture of a cauliflower. There was a faint grayish infiltrate in the cornea and local congestion of the bulbar conjunctiva and episclera.

It was decided to treat the patient by radiation. Nine treatments of low voltage unfiltered x ray therapy were administered in fractionated doses of 600 roentgens every other day up to a total of 5,400 roentgens in 18 days. At the end of this course of treatment the tumor had disappeared entirely leaving only a faint infiltrate a few small deep vessels and a very shallow depression at the site of the growth. JOSEPH S. GOTZ, PHILLIPS THYNGSTON and MORRIS WATSMAN. *Am. J. Ophth.* 1947 30 1485

A Consideration of Aniridia with a Pedigree. P. H. BEATTIE. *Brit. J. Ophth.* 1947 31 649.

The author discusses aniridia with a pedigree. This congenital anomaly was treated in 2 or 3 patients of a family and their various blood relatives were visited to observe and record the condition of their eyes.

Thirty-one patients were found with bilateral abnormalities of the iris. 4 patients had coloboma of the iris with or without hypoplasia of the iris. 10 presented either partial or complete aniridia of both eyes and 12 presented bilateral aniridia and ectopia lentis.

Three clinical types of cases have been described. 1. Patients with coloboma and/or hypoplasia of the iris. These patients have no disability; their visual acuity is normal and they show no tendency toward the formation of lens opacities nor toward increase of their intraocular pressure.

2. Patients with simple aniridia. They present photophobia and poor vision. They develop scattered opacities and deterioration in vision as they grow older.

3. Patients with aniridia and ectopia lentis. These patients present photophobia and their visual acuity is poorer than that of patients with uncomplicated aniridia.

Only affected members of the family transmit the disease while normal children invariably have normal offspring. It is a dominant characteristic in

ml indicated that significant lasting impairment may extend to brightness levels of 50 ml or less.

4. All patients showed a temporary impairment in acuity and in brightness sensitivity at 2 ml after previous adaptation to 2000 ml. None showed lasting impairment after adaptation to the low brightness.

5. Impairment in foveal sensitivity to flicker at high intensities was less marked when the brightness of the surrounding fields was 1 ml and only the 1 degree test field was of high brightness.

6. Increase in the length of the dark phase of the flicker cycle produced less than the normal increase in sensitivity to flicker at the fovea. This was true at low as well as at high brightnesses of the test field.

7. The findings in patients studied for more than 3 months while on tridione indicate that tolerance to the visual side effects develops with continued medication. Patients reexamined after the drug was discontinued showed no evidence of any visual impairment after 10 weeks without tridione.

The action of tridione on the visual mechanism probably does not occur posterior to the chiasm since exposure of one eye to a high brightness does not produce these effects in the unexposed eye. If the action were at the level of the optic nerve it is unlikely that cone fibers alone would be affected. It seems probable, therefore, that the drug produces its effects at the retinal level. For the most part the phenomena suggest that the neural layers of the retina rather than the photochemical processes are involved. Studies on animals of the effects of tridione use of the electroretinogram measuring the optic nerve discharges and so forth might therefore be of aid in explaining the mechanism of the visual defects.

J. WOODHULL OVERTON M.D.

Disseminated Lupus Erythematosus FREDRICK C. CORDON and SAMUEL D. AITKEN Am. J. Ophth. 1947 30 1547

The authors report the ophthalmoscopic findings in a case of acute disseminated lupus erythematosus in a woman 36 years of age. The patient was observed clinically for a period of 6 months before fatal termination.

Examination revealed the presence of cotton wool like exudates with small irregular and flame-shaped hemorrhages. The disk was edematous. The vascular changes were most striking: the veins were dilated and irregular in caliber and associated with perivascular thickening and with small isolated thrombooses; the arterioles presented a spotty and disseminated distribution of markedly irregular localized narrowings, some occlusion perivascular thickenings and arteriosclerosis.

Microscopic examination revealed exudates, subintimal thickening and sclerosis of the arteriolar and arterial walls with narrowing of the lumina and wide spread vascular occlusive lesions. Intimal endothelial changes were absent.

No single lesion or combination of lesions is considered pathognomonic of lupus erythematosus. Toxic retinitis is the most typical picture.

General manifestations of the disease include, in addition to the lesions in the skin a prolonged low grade fever which fluctuates irregularly changes in the endocardium renal involvement leucopenia anemia loss of weight asthenia marasmus cachexia, lymphadenopathy hepatomegaly embolic and thrombotic phenomena in the gastrointestinal tract, pulmonary infections arthritis and arthralgia, ulcerative lesions of the mucous membranes. The disease may affect all age groups and especially women between puberty and the menopause. Its etiology is unknown.

EAR

The Nature of the Vestibular Stimulus. L. B. W. JONAKES and J. J. GROEN J. Lar. Otol., Lond. 1946 61 339

The thesis is presented that the vestibular organ distinguishes only between the stimuli of (1) rotational acceleration and (2) linear acceleration and that contrary to commonly accepted interpretations it does not differentiate between dynamic (movement) and static (gravity) stimuli. In support of this view experimental data is given to show that all types of linear acceleration (gravity centrifugal force accelerated linear movements) create the same qualitative and quantitative response in humans. There are two different organs analyzing these stimuli in the vestibular apparatus. This observation is confirmed by (1) the power of discrimination of linear and angular acceleration which persists after destruction of one labyrinth and (2) the striking difference in indication time and after sensation when angular and linear stimuli are separately measured. The indication time is the length of time required for the sensation of either rotary or linear acceleration to reach a maximum.

JOHN R. LINDRAY M.D.

Healing of Experimental Labyrinthine Fistulae: Further Observations J. R. LINDRAY Arch. Otol. Chlc. 1947 46 584

The present report is a continuation of one made a year earlier and the various factors influencing osteogenic closure of a labyrinthine fistula are discussed. The author states that success in preventing osteogenic closure depends on a number of factors. Removal of bone dust and endosteum was essential since these could not be separated in the mastoid cavity, or one in which the covering graft degenerated always closed, usually within 2 to 3 weeks. In all fenestras which had been kept open permanently there was found a thin fibrous attachment while in those developing osteogenic closure, a thick layer of fibrous connective tissue was observed between the canal and the flap in which bone was irregularly being laid down. In no case was an open fistula maintained in the monkey unless the membranous labyrinth was present and closely united to the flap or graft.

herited from affected members of a family in approximately 50 per cent of the cases. Although the condition is not accompanied by any skeletal abnormalities, such as those associated with congenital dislocation of the lens (arachnoidecty) the following defects were encountered in the family: excessive fat, a lazy good humored temperament (suggestive of pituitary dysfunction) and a physiologically small type of sella.

Treatment depends on the type of case. No treatment is required for patients with colobomas and/or hypoplasia.

In cases of aniridia the photophobia may be relieved by wearing dark glasses by contact lenses designed with an artificial iris and a central pupil of normal size, or by tattooing of the cornea to eliminate peripheral rays of light. If glaucoma develops trephining may be performed to relieve it however it is not generally effective. Eyes with aniridia have a predisposition to early lens changes.

For the patients with aniridia associated with ectopia lentis photophobia may be relieved by wearing dark glasses and vision may be improved by correction of the error of refraction.

The author concludes that it is the ectopia lentis associated with the aniridia that is responsible for the high percentage of glaucoma in this series of cases. To prevent the possible development of glaucoma needling rather than the more hazardous procedure of removing the lens (extraction) is advocated in the hope of accomplishing rapid absorption of the lens. If the tension becomes elevated after absorption a trephine operation should be performed.

JOSEPH ZOCCERMAN M.D.

Transplantation of the Vitreous. S. MUKL GARTNER and BAURO S. PRITTSKY. *Arch Ophthalmol* 1947; 38: 487

It has been found that the human eye can tolerate the removal of up to 0.6 c.c. of vitreous without apparent damage. The authors experimenting on young albino rabbits, studied the amount of vitreous removal that was feasible as well as the transplantation of vitreous and its substitutes.

They found that simple withdrawal of 0.3 c.c. produced only a transient conjunctival flush however withdrawal of 0.4 c.c. or more of vitreous produced hemorrhages on the iris and retina and sometimes in the vitreous with disastrous final results. Histological examination of eyes from which 0.9 c.c. of vitreous had been withdrawn showed extremely dilated intraocular vessels with extensive hemorrhages into the various structures and spaces of the eye. Removal of vitreous which was immediately replaced by other vitreous still caused degenerative changes. However by the device of a double needle and syringe which could remove old vitreous and inject new vitreous simultaneously little hypotony was produced and the procedure was well tolerated.

The best substitute for vitreous was vitreous from another eye (rabbit kitten or human being) and amounts up to 1 c.c. were successfully transplanted.

Saline solution could be substituted in small cases. A blood vitreous mixture was withdrawn with in a vitreous transplantation within 4 hours after its injection. If the blood remained several days it coagulated and could not be withdrawn. Vitreous preserved under refrigeration for a week became cloudy but could be injected without undue trouble.

ROBERT H. JOHNSON, M.D.

Visual Effects of Tridione. LOUISE L. SMITH and ANITA P. GILCHRIST. *Am. J. Ophthalmol* 1947; 30: 154

A new synthetic compound, "tridione," has recently been used as an anticonvulsant in the treatment of epilepsy. A number of papers describing the results obtained with this new drug mention the fact that patients frequently complain of visual symptoms associated primarily with high blood levels. Such symptoms are reported by a majority of adults and adolescents, only occasionally by younger children.

The purpose of this paper is to report the results of a series of tests of visual functions which provide further information as to the nature of the usual visual phenomena associated with tridione therapy.

Tests of the visual function were made prior to and two brightness levels, 2 millilamberts and 2,000 millilamberts, and emphasis was placed on measurements of the rate of recovery of visual function after continued exposure to each brightness level. Tests of both visual acuity and differential brightness sensitivity at the fovea were used in the experiments. Supplementary studies included determination of the light threshold tests of color discrimination at high intensity and tests of sensitivity to flicker.

The dosage of tridione was 2 gm. per day in 1 case, and 3 gm. per day in 1 case. The studies were from 2 to 9 months.

The significant effects of tridione on visual function demonstrated in this study may be summarized as follows:

1. Acuity brightness sensitivity color discrimination and sensitivity to flicker showed temporary impairment in all patients tested when both the foveal test field and a surrounding area of 6 to 10 degrees were illuminated to a high brightness. While these findings all point toward impairment in function of the foveal cones at high brightnesses, supplementary tests indicated that the defect was not a localized central scotoma, but involved cone function throughout the entire retina.

2. With continued exposure to the high brightness there was gradual improvement in visual function. In 5 of 7 patients, acuity and brightness discrimination reached normal values after about 10 minutes. Sensitivity to flicker although it improved, continued to show significant impairment after long adaptation to the high brightness in patients who had recovered normal acuity and normal brightness sensitivity.

3. Two of the 7 patients showed a lasting impairment of both acuity and brightness sensitivity at 2,000 ml. Tests of acuity at brightness below 2,000

Advanced age a poor general condition repeated operative failures and aplasia of the palate form contraindications to operation. In cases presenting these factors modern prostheses furnish excellent results. The author favors relatively large instruments. He uses nonabsorbable suture material such as nylon or cotton. Whenever deep anesthesia is not required local and block anesthesia is employed. Anterior and posterior palatine branches are injected and the staphylopharyngeus mucosa is infiltrated with the anesthetic. For general anesthesia the author uses ether and oxygen employing intratracheal intubation. Morphine and atropine are given preoperatively. The patient is operated on in Rose's position.

The operative technique is based on the mobilization of mucoperiosteal and muscular flaps.

Success depends on gentle handling of the tissues, complete dissection of the flaps and proper immobilization of sufficient duration. Long lateral incisions according to Dieffenbach's method with Ernst's prolongations are made. Blair's mucosal sutures in the form of a sagittal U are used. Nasal mucosal muscular and aponeurotic and oral mucosal planes are formed. All adhesences are severed to allow the "push-back."

After the operation an iodoform sponge with balsam of Peru is placed over the wound and is kept in place by means of a molded prosthesis. The latter is attached to the teeth. In infants the prosthesis is kept in place by means of a heavy thread which is carried through the nose and tied over the columella.

JOSEPH K. NARAT, M.D.

Survey of Pathologic Specimens from the Oral Regions Seen at the Army Institute of Pathology during World War II. JOSEPH L. BERKMAN. *Mil Surgeon* 1947 101 363.

Fifteen cases of Ludwig's angina have been recorded which indicates that, although rarely seen the condition remains a problem because of its serious prognosis.

Only 3 cases of Mikulicz's disease were seen. The intensity of infiltration of lymphatic elements was a striking feature. The gland acini become widely separated and atrophic while the ducts undergo hypertrophy in this condition.

Leucoplakia can be classified histologically into two types: (1) the verrucal form, and (2) a leucoplakia which shows less keratotic activity and more widespread involvement. About three-fourths of the lesions reported were on the lips and of these, almost all occurred on the upper lip. Primary syphilitic lesions of the lip may grossly resemble the infiltrating type of carcinoma.

Oral tuberculosis occurs most frequently on the tongue, lips and pharynx in the form of rough, moth-eaten ulcers which may resemble aphthous ulcers and squamous cell carcinoma. Histological differentiation from sarcoid is extremely difficult.

Because of confusion concerning the term epulis, its use has been discontinued. Peripheral giant cell

tumors (giant cell epulis) arise from the periodontal membrane and have a high incidence of recurrence. Granuloma pyogenicum cannot be differentiated histologically from pregnancy tumors of the gums.

Of the 38 salivary gland mixed tumors which occurred on the lips 35 occurred on the upper lip. Eight hundred and twenty-seven squamous cell carcinomas of the lip are recorded; they may be classified into papillary and ulcerating forms. One of every 5 specimens submitted to the Institute was malignant and one of every 8 specimens was a squamous cell carcinoma of the lip. Certain factors peculiar to military existence may be responsible such as excessive radiation, wind, and dust.

JOHN R. LINDSEY, M.D.

Interosseous Wiring in the Treatment of Fractures of the Mandible. STUART GORDON. *Arch. Surg.* 1947 55 660.

Interosseous wiring as a method of treatment in suitable fractures of the mandible has been used by the author in 48 fractures in 46 patients.

Wire suture of the fractured mandible is applicable in fractures of the edentulous mandible fractures having an edentulous posterior fragment, multiple fractures (for stabilization of the main fracture) bilateral fracture through the mental foramina with downward displacement of the central fragments gun (or shell) wounds (for stabilization when a portion is missing) and m fractures at the base of the condyle with displacement. The procedure used by the author is as follows:

An incision is made below the mandibular line. No attempt is made to protect the inframandibular branch of the facial nerve as recovery uniformly has followed its injury. The fracture ends are freed of soft tissue on both surfaces for about 3/4 inch. Two holes are drilled in each end as in Figure 1. A high speed drill should not be used. Twenty six gauge stainless steel wire is threaded through the upper two holes as a simple suture. It is not tightened until the other wire is in place. It was found that some degree of displacement of the posterior fragment recurred if the lower wire was also used as a simple suture. Therefore this wire is placed as a figure 8 with the crossed portion under the edge of the fragment not tending to become displaced. This prevents any postoperative shift. The wires are tightened with the fracture reduced.

Fig 1 (Gordon)

As it is believed that the least possible movement at a fracture line, particularly when foreign material is present, aids the development of solid union with a minimum of complication. Intraoral fixation was used as well in 43 patients, pins and a Gunning splint in 1 patient each and no secondary fixation was used in the forty-sixth patient.

If a tooth in the line of fracture was rather loose or fractured or had a denuded root in the fracture line, it was extracted before the incision was made. If possible an intraoral dental roentgenogram was taken, since the information obtained from it is of more value than that obtained from a large roentgenogram.

Six of the 48 fractures were simple. Postoperative infection did not develop in any of these. There were 10 postoperative infections in the remaining 42 compound fractures wired. Two of these were serious, resulting in osteomyelitis with sequestration in one case, and union in the other. One of the other 8 infections produced abscesses involving soft tissue only which had to be drained but caused no further damage.

Union occurred in the cases without infection in an average of 44 days. In cases with infection union occurred in an average of 54 days.

In the cases of condylar fracture wiring was done in order to reduce the fracture and to maintain the position. It was thought by the author that the functional result obtained was no better than that obtained from the usual methods of treatment so open reductions were abandoned in this type of fracture.

It was thought from the experience obtained in these cases that the use of interosseous wiring in the treatment of fractures of the mandible was of value in maintaining edentulous fragments in anatomic position in stabilizing a mandible when a portion was missing or when multiple fractures were present and in maintaining accurate reduction of the central fragment when fractures were present in both mental regions, but it was of questionable value in the treatment of fractures of the condylar process. Interosseous wiring makes it possible to obtain and maintain a more accurate reduction of the fracture than that obtained by any other applicable method of therapy. This method should never be used when acute infection is present but its use is not contraindicated in compound fractures free of clinical signs and symptoms of infection. JOHN E. KARASIM, M.D.

Intraosseous Tumors of the Maxilla. H. BLEKHA and H. B. UNGER. *Am. J. Orthodont.*, 1947, 33: 85.

The authors describe 2 intraosseous tumors of the maxilla, and state that tumors of this type are not of common occurrence.

One patient, a 45 year old edentulous female, presented a history of sudden attacks of pain in the right cheek which had been occurring for a period of 3 years. The pain was associated with swelling and "black and blue" discoloration of the face. Physical

examination revealed a hard swelling of the right upper alveolar ridge, extending toward the hard palate. X-ray films showed an osteoporosis of the alveolar ridge of the maxilla and a tentative diagnosis of a localized osteitis fibrosa was made. Following biopsy, a diagnosis of adamantinoma was made. Radical operation consisted of complete removal of the alveolar process and the hard palate on the right side and complete excision of the tumor. The maxillary sinus was not involved. Microscopy established a final diagnosis of adenocarcinoma of mixed tumor type. There had been no recurrence 5 months after the operation.

The second patient was a 16 year old white female who had experienced two attacks of swelling and tenderness of the left cheek and left upper jaw within the preceding year. During one of these attacks an incision was made to evacuate pus. Physical examination showed swelling and tenderness of the left cheek and alveolar process of the mandible. Transillumination revealed a dark antrum on the left side and roentgenograms showed a densely opaque mass within the left maxillary sinus containing several malformed dental structures. A tentative diagnosis of odontoma was made.

At operation the anterior wall of the maxillary sinus was resected and the tumor was removed from the walls of the sinus. The antrum was drained through the nose and the resultant fistula healed within 3 weeks. Microscopy revealed a compound odontoma. X-rays taken 1 month after operation showed a mass within the antrum which apparently was a broken off piece of the original tumor that had blended with the antral wall. The patient was symptom free and roentgenograms taken 6 months later revealed the remnant of odontoma to be somewhat smaller. ELMER D. BLOOMENTHAL, M.D.

NECK

Syndrome of Avellis: A Review of the Literature and Report of a Case. SAMUEL L. FOX and G. B. COOK, JR. *Arch. Otolaryng.*, Chic., 1947, 45: 773.

Since Avellis, a German laryngologist, first published his series of 10 cases of a syndrome which has been given his name in 1891, less than 30 cases have been reported in the available literature.

The syndrome of Avellis comprises a hemiparesis of the larynx and soft palate on the same side and, according to Jackson and Jackson, "there may be loss of pain and temperature sense on the opposite side including the extremities, trunk and neck." This complex syndrome frequently results from a pathologic condition at the jugular foramen although in some of the cases reported it was supposed to be of bulbar origin. Since the vagus nerve is closely associated with its neighboring cranial nerves at this level numerous combinations and modifications are possible and have been described.

To appreciate the syndrome of Avellis fully one should briefly review the anatomy of the vagus nerve

as it emerges from the jugular foramen is accompanied by and contained in the same sheath of dura mater with the accessory nerve and only a fibrous septum separates them from the glossopharyngeal nerve anteriorly. The accessory nerve on making its exit from the jugular foramen separates into a cranial and a spinal portion. The vagus nerve after its exit from the jugular foramen is joined by the cranial portion of the accessory nerve and enlarges into a ganglion swelling called the ganglion nodosum. Through this the fibers of the cranial portion of the accessory nerve pass without interruption and are distributed chiefly to the pharyngeal and are laryngeal branches of the vagus nerve. Thus the pharyngeal branch of the vagus nerve consists principally of filaments of the cranial portion of the accessory nerve. Its branches are joined by branches from the glossopharyngeal sympathetic and external laryngeal nerves to form the pharyngeal plexus. The plexus supplies the muscles of the pharynx and soft palate except the tensor veli palatini which is innervated by a branch of the trigeminal nerve. The external branch of the superior laryngeal branch of the vagus nerve supplies the cricothyroid muscle and gives off branches to the pharyngeal plexus and to the inferior constrictor muscle of the pharynx.

The lesions which may produce the syndrome can be classified etiologically as vascular inflammatory, neoplastic, traumatic, and toxic.

One case is reported because of its apparently unusual causation, i. e. it was secondary to acute mastoiditis. There was complete recovery in this case. Some authors believe it is advisable to discard the term syndrome of Avellis and other similar terms in favor of terms indicative of the site of the lesion. On the basis of this suggestion the case herein reported would be classified as the jugular foramen syndrome.

JOHN F. DELPH, M.D.

Propylthiouracil in the Treatment of Hyperthyroidism. E. PRATT McCULLAGH, RALPH E. HIBBS and ROBERT W. SCHNEIDER. *Am J Med Sc* 1947 314 345.

The authors believe propylthiouracil to be a safe drug for the treatment of hyperthyroidism. No cases of agranulocytosis were seen in 218 patients treated for an average of 8 months and in some instances as long as 14 months. 7 reactions required the cessation of treatment. The action of propylthiouracil is too slow in controlling acute crises in hyperthyroidism and also the hyperthyroidism of acromegaly other all types. Three hundred milligrams per day were found to be an effective dose in more than 95 per cent of the authors' 218 patients. A smaller dose was effective in many and a larger dose was required in less than 4 per cent.

Iodine therapy has been used concurrently with propylthiouracil, and the authors believe that it is definitely indicated as it takes care of some of the symptoms which propylthiouracil does not.

A tentative plan is presented for the use of propylthiouracil with the patients having been graded into four classes.

The first class includes those with small goiters and relatively mild hyperthyroidism.

The second class includes young people with byperthyroidism of mild or moderate degree in which surgery is anticipated thus the iodine is used and acts more rapidly. Propylthiouracil may be used but it is unnecessary.

The third class includes all patients with severe hyperthyroidism, all those over 45 years of age and those with complicating factors such as a poor cardiac status. For these propylthiouracil is used and when the disease is controlled Lugol's solution is administered.

The fourth class includes patients in whom the hyperthyroidism is complicated by extreme old age and cardiac or other complications. For these propylthiouracil may be continued indefinitely. At the present time long continued use of propylthiouracil appears warranted in some patients.

RICHARD J. BENNETT, JR., M.D.

Treatment of Graves Disease with Radioactive Iodine EARLE M. CHAPMAN *West J Surg* 1946 56 47

The author describes the historical background of radioactive isotopes. Hertz, Roberts Evans and others established the physiologic facts for the rational use of radioactive iodine as a single therapeutic agent.

The radioactive iodine used in this series was prepared by the nuclear bombardment of tellurium in

the Massachusetts Institute of Technology cyclotron. The principal isotopes used were I^{131} with a half-life of 12 hours, and I^{125} with a half-life of 8 days. The 8 day iodine constituted about one-tenth of the total amount. Approximately 80 per cent of radioactive iodine is absorbed by the thyroid within a few hours after oral administration and most of that not absorbed is rapidly excreted by the kidneys.

Fifty per cent of the total radiation dose from the 12 hour iodine is delivered in the first 12 hours and 90 per cent within 36 hours. The tissue dose per hour is mainly due to the 12 hour isotope for the first 2-5 days thereafter the 8 day isotope adds approximately 2 per cent each day to the total radiation previously delivered by the 12 hour isotope. The basal metabolism rate curves of the 23 patients who responded to a single dose show that the normal basal metabolic rate was reached on an average of 33 days after treatment.

From his experience in treating 45 patients with diffuse goiters and hyperthyroidism the author believes that radioactive iodine with a half life of 12 hours is an effective single therapeutic agent. The possible late toxic effects will have to be observed with the passage of time. Contraindications to its use now seem to be pregnancy beyond the first month and disease of the kidneys.

ERNEST D. BLOOMFELT, M.D.

Two Cases of Tuberculosis of the Thyroid Gland
(Due casi di tubercolosi della ghiandola tiroidea)
GIACOMINO COCCHI. *Arch. ital. chir.* 947 69. 23.

The author reports 2 cases of tuberculous of the thyroid gland. The first patient had a cold abscess which had developed at the bottom of a thyroid adenoma and was secondary to a healed primary pulmonary lesion. Removal of the adenoma and the abscess resulted in a complete cure. In the description of the histologic picture, it was interesting to note the role of the tubercles situated between the follicles, and also the richness of the giant cells.

The second patient had a massive caseous tuberculous of the thyroid gland, corresponding to Lenormant's classification. This focus was secondary to an active focus in the tibia and the tarsus. Extirpation of the thyroid tumor followed by drainage resulted in a cure in 6 months.

In both cases, Koch's bacillus was identified by biological methods.

ARMANDO F. CROCI, M.D.

Cancer of the Thyroid Gland. Anatomical Types, Evolution, and Results of Treatment in 23 Cases
(Cáncer de la glándula tiroidea. Tipos anatómicos, evolución y resultados alejados del tratamiento en treinta y cinco casos)
ANTONIO ECHES and ENRIQUE P. VIACAVA. *Bo. Inst. dta. quim. B. Alir.* 947 3. 24.

From observations on 35 cases of cancer of the thyroid gland the authors hoped that some therapeutic orientation could be adopted on the basis of an anatomoclinical classification. The variability of the patients' clinical physiognomy and the diver-

sity of the histomorphologic aspects attracted some attention. The disparity in the evolution, however, was more significant.

Correlation of the evolution of the disease with the different grades and types was accomplished by means of the strict histomorphologic methods adopted. Three anatomic types were recorded: (1) papillary adenocarcinoma (17 cases), (2) malignant adenoma (11 cases), and (3) anaplastic epithelioma (7 cases of this most malignant condition which manifested itself in the multiple metastases found).

There was no uniformity in the treatment of thyroid carcinoma. In the papillary adenocarcinoma the operation was in direct relation to the grade of the tumor encountered and the invasiveness of the process. In the malignant adenomas, the procedure was limited only by the progress of the neoplasm into the neighboring structures. The cases of anaplastic epithelioma were subjected to little definitive surgery because of the metastatic character of the disease. Block dissection of the tumor and radical resection of the neighboring glands were done in all cases in which this was possible and followed by irradiation therapy.

STEPHEN A. ZIEGLER, M.D.

Modern Trends in Surgery of the Thyroid Gland.
FREDERICK A. BOTTEL. *Surg. Clin. N. America* 947 27. 364.

The diagnosis and treatment of goiter, thyroiditis, and malignancy of the thyroid gland are considered. All cases of goiter are studied preoperatively and are considered from both the physical and laboratory standpoints. Both iodine and thiouracil are believed to be of value in the treatment of hyperthyroidism.

The author presents certain statistics on thiouracil which show that its use in some cases has been disappointing, however, thiouracil has been found to be of definite value in the preoperative preparation of patients with severe hyperthyroidism.

Not infrequently marked disturbances in calcium and phosphorus metabolism occur in hyperthyroidism. Occasionally this (roentgen) finding leads to the diagnosis of hyperthyroidism in cases of long duration with mild or obscure symptoms. Disturbances in carbohydrate metabolism occur in about 80 per cent of patients suffering from hyperthyroidism. Of this number only about 5 per cent have diabetes. When severe diabetes and hyperthyroidism exist it is necessary in about half the cases, to perform a thyroidectomy in two stages. In cases in which foci of infection exist, the operation needed to eradicate the infection should not be performed until from 4 to 6 months after the thyroidectomy. Some of these foci may precipitate severe hyperthyroidism.

Apathetic hyperthyroidism is discussed. In some patients, studies over a long period of time are necessary before an accurate diagnosis can be made. These patients are poor surgical risks, and they require careful, prolonged preoperative preparation, and operation in two stages.

Liver damage and diminished liver function in patients suffering from hyperthyroidism contribute greatly to the surgical risk and operative mortality of thyroidectomy. Studies of liver function are carried out on patients with severe hyperthyroidism or on those who are in crisis. The bromsulphalein and hippuric acid tests are used. These tests serve only as a guide in the treatment of this complication. Routine therapeutic measures which have proved to be of value are intravenous glucose with insulin, bile salts, liver concentrate and glycane.

The optimal time for operation seems to be when the basal metabolism falls to normal or near normal. The determination of blood iodine seems to be more satisfactory in estimating the degree of hyperthyroidism. If the pulse rate remains below 100 hyperthyroidism is usually well under control. If the patient has lost 20 pounds or less he is ready for operation when he has regained one third or more of his weight loss.

The addition of a well trained physician-anesthetist to the operative team has also been helpful in cutting down the mortality of thyroidectomy.

There is approximately a 2 to 3 per cent recurrence of symptoms of all patients operated on for hyperthyroidism.

Hypothyroidism and hypoparathyroidism and their treatment are discussed as well as paralysis of the vocal cords due to injury to the recurrent laryngeal nerves.

Chronic thyroiditis in the form of Riedel's struma and Hashimoto's disease is discussed. Riedel's thyroiditis occurs in either sex, usually in individuals under 40 years of age, while Hashimoto's disease is most always found in women in the later decades of life. The entire thyroid gland is involved in Hashimoto's disease, while in Riedel's struma the process is confined to one lobe in approximately 30 per cent of the cases. In Hashimoto's disease the process does not extend beyond the gland, whereas in Riedel's struma it may break through and extend beyond the capsule. The hardness in Riedel's struma may be very easily mistaken for malignancy. If there is no evidence of malignancy in the microscopic diagnosis of either Riedel's struma or Hashimoto's type of thyroiditis, only one lobe should be removed. In this way hypothyroidism may be postponed.

Acute thyroiditis is usually secondary to acute upper respiratory infection. Occasionally a localized abscess results and this is treated by incision and drainage.

Approximately 90 per cent of carcinomas of the thyroid gland develop in a pre-existing adenoma, thus all adenomas are suspected of being or becoming carcinomatous. Radioactive iodine may be used in two ways—first as a tracer to detect the presence of metastatic lesions by means of the Geiger counter and second to treat malignancy. It has been demonstrated that the radioactive iodine is picked up only by the metastatic lesion in which the tissues are carcinomatous.

RICHARD J. BEDONNET JR., M.D.

The Treatment of Lymph Node Metastases from Intraoral Carcinomas with Special Regard to the Indications for Total Neck Dissection ROLF WEINZ, *Acta radiol. Stockh.*, 1947, 28, 367

The author discusses the published reports of other authors with regard to the treatment of cervical lymph node metastases and presents in detail, the results obtained in the treatment of 386 patients with histologically verified oral carcinoma at the Norwegian Radium Hospital during the 10 year period from 1932 to 1941 inclusive.

Table I shows that 58 per cent of the lesions were in stage 1, 20 per cent were in stage 2 and about 22 per cent were in stage 3.

Broder's method of classification has been adopted. Table 2 shows the number of patients in each group according to the histological examination. The borderline between these groups is not marked but, as will be seen from the table, the greater number of patients (332 or 86 per cent) come into the groups of highly differentiated squamous cell carcinomas.

The method of treatment was as follows. The primary lesion is treated with teletherapy from 1 to 2 fields or more according to the size of the tumor and its situation. After a period of 6 to 8 weeks the lesion is re-examined and if any part of the tumor remains it is coagulated or intubated with radium needles or both. Treatment of the regional lymph node areas commences at the same time that treatment of the primary tumor is instituted. Prophylactic neck dissection is not performed in stage 1 tumors nor is prophylactic neck dissection performed right away in cases in which the lymph nodes are suspected of being cancerous (stage 2). If any part of the tumor still remains after a period of 8 weeks, total neck

dissection is performed. The indications for operation on tumors in stage 3 are subject to greater individual consideration. With increased experience the tendency has been to decrease rather than increase the indications for neck dissection.

The results obtained in the treatment of intraoral carcinomas during the 5 year period are shown in Table 3. Freedom from symptoms has been attained for 5 years in 26 per cent of all cases. 1 carcinoma localized in the free part of the tongue. The main problem in the treatment of intraoral carcinoma is that of treating the primary tumor. Among 203 patients with intraoral carcinoma, 263 died from the effects of the primary tumor, 31 died symptom free, from intercurrent disease, and 8 died as a result of distant metastases without local recurrence. It is suggested that in a great majority of cases the primary tumor is incurable with present methods of treatment. In 234 of 263 patients who died of cancer the primary tumor was found to be a contributory cause of death.

Only 19 patients died of regional lymph node metastases with the primary tumor symptom-free, or probably curable.

A total of 224 patients without lymph node metastases were admitted to the hospital. Later 18 of these patients had operable nodes and 30 had inoperable nodes. Inoperable lymph node metastases developed in less than 33 per cent of these patients. Nine of the patients might have benefited from prophylactic neck dissection. To prove, however, that prophylactic neck dissection was necessary in all 9 cases, it would have been necessary to carry out the procedure in 224 patients.

In the author's opinion prophylactic neck dissection is not indicated in intraoral carcinoma (stage 1) but carcinoma of the tongue calls for special attention.

In stage 2 neck dissection would have had to be performed on 65 patients in order to obtain its possible advantage in 5 recurrences. It is still the prognosis of the primary tumor which decides the fate of the patient. Prophylactic neck dissection is not indicated in stage 3 tumors. The author believes that something further must be done to reduce the mortality from primary tumors. The results presented here are comparable to those obtained in similar series by other authors. RICHARD J. BRONCK, JR., M.D.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Cerebral Arteriography (Arteriografía cerebral) BAUDE
210 VILLARUYA. *Anales med Méx* 1947 8 15

The author's investigation is confined to arteriography of the internal carotid artery and phlebography. Cerebral arteriography was introduced by Moisés in 1927.

The common carotid artery was pierced after the usual preparation of the skin with tincture of iodine and preliminary administration of morphine and barbiturates. Pentothal sodium intravenous anesthesia was used. The author employs a 17 gauge 10 cm. needle, connected with a manometer and a syringe. An injection of several cubic centimeters of sodium citrate is followed by an injection of from 15 to 20 c.c. of 35 per cent solution of Winthrop's preparation novayin. The author prefers this medium eliminated because the latter is not completely system and is radioactive. The injection is made within 1 or 2 seconds at the most. The first roentgenogram is taken just before the injection is finished and two more pictures are taken in rapid succession 200 ma. and a 36 inch distance are used for taking the pictures.

The main indications for cerebral arteriography are tumors angiomatosis aneurysms arteriosclerosis and thrombosis.

The author reports 6 cases in which cerebral arteriography was employed and proved useful in the diagnosis.

JOSEPH E. NARAT M.D.

The Treatment of Focal Epilepsy by Cortical Excision WILDER PENTFIELD and HARRY STEELMAN
Ann Surg 1947 126 740

Focal epileptic discharge can now be localized in all areas of the cerebral cortex. Excision of partially damaged convolutions adjacent to meningocelebral scars or in areas of brain atrophy has proved to be effective treatment. This is demonstrated in this review of the results of radical surgical therapy of atrophic epileptogenic lesions of the brain of those who were operated upon in the 6 year period from 1939 to 1944. The time of follow up varies from 1 to 7 years.

A total of 76 patients were operated on for epilepsy. Only 1 patient died as a result of the operation his death being caused by an infected extradural hematoma and meningitis. The case mortality was thus 1.3 per cent and the operative mortality 1.3 per cent. Cortical excision was performed in 59 of the 75 cases to be followed up and craniotomy without excision in 16.

A variety of lesions may give rise to cerebral seizures, and brain lesions of many types are apt to produce some local destruction of the nerve cells. After

such destruction neuronal regeneration does not occur in the central nervous system. However unless all circulation to the part is destroyed the neuroglia react in a positive way producing gliosis. Destructive processes are also associated with phagocytosis of myelin and other material. The end result of these changes is gross atrophy of the involved convolutions.

The following pathological lesions are discussed: meningocelebral atrophy, local cortical atrophy, local microgyria, expanding lesions, cysts and other abnormalities. The histologic aspects of the epileptogenic focus are presented.

Patients who suffer from epileptic seizures can be studied by means of a simple classification.

1. *Idiopathic epilepsy*. In this class the electroencephalogram shows a bilateral disturbance in brain potentials of characteristic form. The seizure begins with loss of consciousness and when small is of the type recognizable as absence or petit mal. There is often an epileptic tendency in the families of such patients. For idiopathic epilepsy there is no effective surgical therapy.

2. *Cerebral seizures*. When the attacks are not clearly of the above type the cause should be sought and the pattern of attack studied. If the cause proves to be due to hypoglycemia, a degenerative condition of the brain or systemic disease, surgical therapy is likewise not indicated and the diagnosis is expressed for example as cerebral seizures caused by hypoglycemia.

3. *Focal cerebral seizures*. When the beginning of the seizures is clearly identified and if the cause is obviously not hereditary, metabolic, degenerative, or neoplastic, then the diagnosis of focal cerebral seizures may be made. If conservative treatment does not control the attacks then surgery may be given due consideration. In most cases the patient should be hospitalized for study so that the suitable cases may be selected.

Evaluation of the focal epileptic is also dependent upon the nature of the attack pattern: roentgenography, pneumoencephalography and electroencephalography.

4. *Discussion*. The nature of the operative procedure and excision technique is given and several excellent photographs illustrating the technical features are presented.

Of the 59 patients who had excision 15 had no further attacks from 1 to 7 years after operation while 18 had 1 or 2 seizures but considered themselves cured or practically so, therefore 56 per cent of the patients had a successful operation. Sixteen similar craniotomies were carried out without excision and none of these was successful. It therefore seems logical to conclude that epileptic seizures due to cerebral abnormality are not helped by craniotomy unless radical excision is carried out. Removal

of adhesions, decompression or closure of cranial defects has no effect upon the attacks unless the proper excision is carried out. The elements of success or failure in the excision series are to be sought in an analysis of the nature of the lesion, the methods of study and the technique of removal.

The cause of the original lesion in this series was most often head injury—birth injury and local infection were the second and third most frequent causes. The cause was unknown in 19 per cent of the cases which were subjected to excision and in 65 per cent of those in which the results of explorations were negative. The duration of attacks before operation had little or no influence on the outcome.

It is interesting that when the cause was head injury or infection, the onset of seizures was early. The beginning of attacks in these cases came within 5 years in 4 of 5 cases. On the other hand, when the cause was birth injury the onset of seizures was longer delayed. The beginning of attacks came after the age of 5 in 4 of 5 cases. It would seem therefore, that during infancy and early childhood a damaged brain is usually slower to develop the epileptogenic mechanism than later in life.

Birth injuries gave the best results from excision (76 per cent). Infectious processes came next with success in 56 per cent, and head injuries third with success in 51 per cent. Excision is equally effective when applied to meningocerebral scars or to simple cerebral foci. Removals in the frontal pole were most successful (73 per cent) and those in the central (or sensorimotor) cortex came next (67 per cent).

When attacks recur after operation and after the patient leaves the hospital the earlier they appear the more gloomy is the prognosis of eventual recovery. When attacks occur in the convalescent period while the patient is still in the hospital, the prognosis of a good result is extremely poor if the pattern of onset is the same as before operation. Attacks that indicate a neighboring gyrus is subject to edema or anoxemia will have a different pattern and may produce less pessimism. If the pattern is the same as preoperatively, an immediate second operation should be considered. Six patients were thus subjected to a second excision and 3 of them were placed in the group with successful results.

As a result of this present analysis the authors conclude that the persistence of a "spike" electrographic focus after operation or the appearance of marked delta electrographic activity near the site of removal should cause the surgeon to consider reoperation.

In preoperative studies, the simpler the electrographic record is and the better it is localized the better the prognosis of a successful excision. The more diffuse the electrographic abnormality the less hopeful is the prognosis. It must be added, however, that a well localized simple electroencephalogram, not supported by pneumographic or other evidence of a lesion, has sometimes led to a useless exploration, i.e., a craniotomy without excision. Excision guided solely by an electrographic abnormality seems to be

a procedure of doubtful value. The uses of electroencephalography during operation (electrocorticography) are still being studied and will be reported upon at a later time.

In conclusion, the surest guide to localization of an epileptogenic zone is the seizure pattern. The greatest supplementary help a surgeon can receive is electrographic study by an expert, and this special method of study has opened a new chapter in the treatment of focal epilepsy. However the electrogram without objective change in the cortex and without the other means of study is not yet to be trusted as the final guide to excision.

Radical excision seems to offer a reasonable possibility of cure (56 per cent) to those who have cortical foci of discharge and whose attacks are not controlled by medication. All patients operated upon within a given period have been included in this report, so that the elements of success and failure may become apparent and thus prepare the way for future advance.

HOWARD H. LAMSTER, M.D.

Some Views on the Glioblastomas according to Scherer (*Quelques considérations sur les glioblastomes multiformes au sein du cerveau*) J. DE BUSCHER, *Bruxelles méd.* 947 7-23 1

The author gives a brief summary of the views of the late H. J. Scherer on gliomatous tumors of the brain. He agrees with the report given by Bailey and Cushing on those which arise from below the tentorium but takes exception to their views on concerning the supratentorial gliomas. The supratentorial astrocytoma is believed to be of quite a different nature from the so-called astrocytoma of the subtentorial region; it is diffuse and inclined to malignant deterioration into what he calls a secondary glioblastoma. Scherer attempted to isolate four groups of cerebral astrocytomas: (a) anterior subcallosal, (b) posterior subcallosal, (c) supracallosal, and (d) callosal; this classification is based entirely on their location. The author denies the existence of an astroblastoma and considers that the oligodendroglioma and polar spongioblastoma are not anatomical entities. He has little quarrel with the analysis of the pinal tumors made by Bailey and Cushing. The papillomas of the choroid plexus are included in the ependymomas. As to the vast group of glioblastomas (primary) constituting 50 per cent of the gliomas, he had been unable to analyze these successfully and was still studying them at the time of his death. There is much less difference between the views of Scherer and of Bailey than the tone of the article would lead one to suppose. De Buscher admits that Scherer's classification cannot pretend to embrace the complexity of the facts any more successfully than the scheme of Bailey and pays tribute to the merits of the latter.

The last half of the article is devoted to a logically unrelated discussion of the clinical differential diagnosis of glioblastomas.

The reader would do well to consult the original Volume I of de Buscher and Scherer (Brussels, 1923).

in which Scherer developed his views systematically. It is unfortunate that he did not live to complete the other volumes of the intended trilogy although perhaps not too much is lost. Scherer seems to have delivered his principal message in the first volume. The second volume was to deal with the tumors of the subtentorial region and the analysis of these tumors made by Bailey and Cushing according to detail. The third volume was to deal with the primary glioblastomas concerning which Scherer had been unable to clarify his ideas.

ADRIEN VEX BRUGNON, M.D.

The Role of Pinealomas in the Causation of Diabetes Insipidus. GILBERT HORRAX. *Ann Surg* 1947 125 785.

In this article the author discusses the role of pinealomas in the causation of diabetes insipidus. The occurrence of diabetes insipidus in some patients with pituitary tumors or other lesions in the immediate suprasellar or chiasmal region has been understood since the original investigations on the antidiuretic effect of the secretion of the posterior lobe of the hypophysis by von den Velden and on the causation of diabetes insipidus following lesions of the hypothalamus by Camus and Roussey. On the other hand the occasional report of marked polydipsia and polyuria in patients with tumors arising from the pineal body and apparently confined to this area, which is so far removed from the supposed source of diabetes insipidus, was until recent years unexplainable.

As to the actual intracranial area responsible for polydipsia and polyuria, there were until very recent years three theories, namely, that it was caused (1) by a lesion of the posterior lobe of the pituitary gland, (2) by an injury to the hypothalamus especially the tuber cinereum, and (3) by interruption of a tract of demonstrated nerve fibers running from the hypothalamus through the pituitary stalk to the posterior lobe of the gland, the so-called supraopticohypophyseal tract.

According to Jones it has been shown that there exists a hypothalamohypophyseal system with an included supraopticohypophyseal tract which operates as a functional unit and that injury to any part of this system causes diabetes insipidus. Since secretion of the antidiuretic principle by the pars nervosa (of the pituitary) is dependent on innervation through this tract, the supraopticohypophyseal tract is a functional unit and injury anywhere along this tract may result in diabetes insipidus.

The diagnosis of a pinealoma or a tumor arising from the pineal body has been made in 17 instances in the author's brain tumor series during the past 14 years. In 12 of the patients the tumor was verified histologically either at operation or at autopsy. In the 5 other patients histologic verification has not as yet been possible but in these cases localizing neurological signs combined with the visible ventriculographic evidence of a tumor projecting into the posterior portion of the third ventricle from the

pineal region has certified the diagnosis beyond any reasonable doubt.

Of the total 17 patients 5 have shown well marked diabetes insipidus. Two of these patients were in the group with histologically verified tumors the lesion in the other 3 having been demonstrated by ventriculography. In 1 patient with histologic verification at autopsy the tumor from the pineal region was shown to have extended through the floor of the third ventricle to involve the hypothalamus and pituitary body which explained the presence of the diabetes insipidus. The other patient whose lesion was verified microscopically had a so-called ectopic pinealoma in the area above the sella turcica without clinical or other evidence of a growth in the pineal region. The diabetes insipidus in this patient was of course easily explainable as in other tumors situated in the neighborhood of the pituitary stalk and contiguous structures. The tumor was removed at operation and the patient's polyuria has been greatly decreased.

The 3 patients whose tumors were demonstrated by ventriculography have all had roentgen therapy directed at the pineal region. In 2 of these patients there has been a significant reduction of the fluid intake and output, and excellent control of the residual situation is maintained by the use of extremely small amounts of pitressin powder snuffed up the nose. This improvement may be due to the fact that the area covered by the roentgen treatment included a portion of the anterior third ventricle and hypothalamic region. The 3 other patients still show a rather marked polyuria but both have accustomed themselves to their difficulty. One of them has received further courses of roentgen therapy directed both toward his pineal and suprasellar areas with no appreciable change in his intake and output. Their general condition has remained excellent for from 6½ to 14 years following roentgen therapy. The diabetes insipidus has been considerably relieved in 1 and probably in 2 of these patients. It is possible that the water imbalance may persist because partial interruption of the nerve tract from the hypothalamus to the pituitary is permanent even though the tumor cells originally causing this interruption have been destroyed by the roentgen rays.

The 5 case histories and a discussion of each are reported in detail.

SPINAL CORD AND ITS COVERINGS

Streptomycin in the Treatment of Meningitis: Report of 27 Cases Treated at the Boston City Hospital. TOM FITZ PATRICK, RODERICK MURRAY, ALBERT O. SKELLEY, and MAXWELL FINLAND. *Ann Int Med*, 1947 27 494.

Haemophilus influenzae is the most frequent of the gram negative bacilli to cause meningitis and it usually strikes its victims in the first 3 years of life. Of the two types of this organism the smooth encapsulated form is much more important than the rough nonencapsulated one. Of 100 patients reported (by the National Research Council) as hav-

ing been given streptomycin, 17 died. Five of the patients developed a streptomycin resistant strain of *Haemophilus influenzae* while receiving the drug.

Other gram negative organisms which are implicated in meningitis are the *Bacillus coli*, *Alcaligenes faecalis*, *Aerobacter aerogenes*, *Klebsiella pneumoniae*, *Pasteurella tularensis*, *Proteus morgani*, *Proteus vulgaris* and *Pseudomonas aeruginosa*. Streptomycin has been shown to be active in vitro against most of these bacilli and it is effective in experimental infections of animals against some of them. Systemic infections with *Brucella* and *Salmonella* have not responded favorably to streptomycin.

Thirty-two patients with tuberculous meningitis have been treated with streptomycin. Thirteen were still alive at the time of the report, but there was a high incidence of neurologic damage.

At the Boston City Hospital Boston Massachusetts, 7 patients with meningitis were treated with streptomycin. Of 16 who had *Haemophilus influenzae* meningitis, 1 died. Eight had a meningitis due to another gram negative organism and of these, 3 died. Three had tuberculous meningitis and 1 of these died.

Untoward reactions attributed to streptomycin therapy were a secondary febrile episode, increase in protein unassociated with an increase in cells, and a macular erythematous rash.

The authors recommend that the drug be administered both intramuscularly and intrathecally. Adults should receive gm. every 6 hours through the intramuscular route and 50 mgm. daily intrathecally. Children should be given 25 mgm. per pound daily through the intramuscular route and from 10 to 5 mgm. daily intrathecally. Sulfadiazine and penicillin may be given in addition to streptomycin if there is an organism which is sensitive to them.

DANIEL ROCK, M.D.

PERIPHERAL NERVES

Regeneration in the Ulnar Median and Radial Nerves. EDWARD HAMLIN JR. and ARTHUR L. WATKINS. *S. & C. N. America* 947 27 52.

The authors point out the still present fact that surgeons lack a common measurement of what constitutes a satisfactory return of function after injury to a peripheral nerve. In their own group of 248 cases, of which 71 were followed long enough to determine with considerable accuracy the end-result, they considered the result good only if as in the case of either the median or ulnar nerve, there was complete sensory regeneration and sufficient motor regeneration to obviate gross impairment of function. If the radial or peroneal nerves were in question a return of motor function was all that was required for such classification.

They did not observe 100 per cent sensory regeneration following the transection of any nerve yet

of the 271 cases 85 per cent were considered to have had a good result.

The greatest number of injuries were to the ulnar nerve predominately at the wrist. In 7 instances gross sepsis took place following surgery but in these patients good regeneration took place so that the authors feel that sepsis played no part in the poor results, wherever poor results occurred. They did not believe that the age of the patient nor the time interval between date of injury and suture were of any importance in the final result.

In an attempt to determine the rate of growth downward in the ulnar nerve they found the figure to be 1.2 mm. per day as an average in 17 patients with ulnar lesions, with extreme ranges between 3.6 and 58 mm. a day. The same general results were obtained in the patients with median nerve injuries, though clinical recovery was probably not so good as in the patients with ulnar lesions, and the rate of growth in the median nerve was somewhat slower than in the ulnar nerve. The poorest results were obtained in their 36 patients with radial nerve injuries, probably because in this group there were several patients with extensive loss of nerve substance.

So far as technique is concerned they do not depart from the usual standards of careful end-to-end suture with fine suture material through the epineurium after careful trimming of the exposed nerve ends. They place the extremity in a cast for 3 weeks after surgery following which physical therapy is begun. The use of tantalum foil nerve grafts, and the suturing of neuromas with nerve stretching have all failed or have been abandoned by the authors.

A good discussion of electrodiagnostic methods is presented.

JOHN MARSH, M.D.

MISCELLANEOUS

The Carotid Sinus Syndrome: Its Surgical Treatment. RICHARD B. CATTELL and MARK L. WELCH. *Surgery* 947 3 59.

Review of the literature on the carotid sinus syndrome suggests a classification under three headings, according to the efferent pathways over which the impulse travels: (1) vagal characterized by bradycardia, asystole, cardiac arrhythmia and hypotension; (2) depressor manifested by vasodilation and fall in the blood pressure; and (3) cerebral with sudden unconsciousness, unaccompanied by fall in the blood pressure or alteration in the pulse rate.

Three cases of carotid sinus sensitivity are reported in which surgical denervation was performed by stripping the common internal and external carotid sinus "nerves" and removing the inter-carotid tissue. Relief of syncope was obtained by this means in each instance.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Two Unusual Tumors of the Sternum. THOMAS J KIMBLE, MARK WHITE, and R W KOUBEK
J Thorac Surg 1947 16 640.

Reports of 2 unusual sternal tumors: a benign giant cell tumor and an apparently solitary plasma cell myeloma, are presented and the surgical treatment is outlined. The available literature on benign, malignant and metastatic tumors, and on some of the inflammatory lesions of the sternum is reviewed and tabulated

JOHN J MALONEY MD

TRACHEA, LUNGS, AND PLEURA

Three Cases of Bronchial Hamartoma. One Being an Endobronchial Polyp (Tres nuevas observaciones de hamartoma bronquial uno de ellos poliposo endobronquial) O A IRIE, R I LATIENDA, and A J MURRAY *Rev As med argent* 1947 61 614

This report gives brief data on 3 cases of hamartoma of the lung which were found at autopsy having been asymptomatic during life

Two of the hamartomas were peripheral in the parenchyma of the lung, being located in the lower lobe. The third was found to be almost completely obstructing a secondary segmental bronchus in the left upper lobe. It was pedunculated and believed to arise from bronchial cartilage

All of the hamartomas contained a variety of histologic components including hyaline cartilage, smooth muscle, fat, and elastic fibers. Two of them contained epithelial elements, and the pedunculated one contained bone and bone marrow. They were considered of benign appearance

HERMAN T LANGSTON MD

Recent Advances in Pulmonary Surgery CHARLES PHILMORE BAILEY, FRANK TROPEA, JR., and LAURENCE H. RUBENSTEIN *Surg Clin N America* 1947 27 1373.

Numerous advances in the management of patients with chest injuries were made during the last war

In the treatment of hemothorax, it has been definitely established that early and repeated aspiration without air replacement favors rapid re-expansion of the lung and reduces the incidence of complications. No limit should be placed on the amount of blood removed at each aspiration as much as possible being removed. In the treatment of complicated constrictive pleuritis and suppurative constrictive pleuritis, decortication is an important procedure. Early thoracotomy with complete evacuation of the pleural space, removal of fibrous membrane from the lung surface, complete re-expansion with positive pressure anesthesia and the use of closed suction drainage offers the only possible cure with out multiple operations and protracted convales-

cence. The use of penicillin parenterally and intrapleurally is an important factor in the brilliant results obtained with this procedure.

In bronchiectasis, with well established anatomical changes and associated persistent infection, there is no chance of cure by conservative measures. Surgical removal of the affected bronchopulmonary segments is the only logical and curative therapy

The treatment of lung abscess is carried out in three phases: (1) prevention, (2) treatment of the acute uncomplicated abscess, and (3) treatment of complicated and chronic lung abscess. Prevention includes all measures which forestall bronchial aspiration which is the important cause of lung abscess. It also comprises treatment during the stage of atelectasis and pneumonitis in an attempt to avoid tissue breakdown and cavity formation. Bronchoscopy, postural drainage and antibiotics and sulfonamides have their greatest value in this stage. In acute uncomplicated abscess (less than 2 months old and consisting of a single cavity) bronchoscopy, postural drainage and antibiotics may be of value. Should no improvement occur, rib resection and cavectomy should be performed promptly. In the establishment of surgical drainage, the abscess should be localized and should be entered without traversing of the free pleural space. Drainage should be established through the area of adherence of the lung and chest wall. In complicated and chronic abscesses more than 2 months old with multiple cavities, atelectasis of the involved region and residual pneumonitis, pulmonary resection offers the best means of cure. Transfusions, antibiotics and conservative drainage are of great value in the preoperative preparation of the patients.

In addition to the general conservative treatment of pulmonary tuberculosis, the surgical methods employed are collapse therapy, drainage and excision. Artificial pneumothorax is the most commonly used collapse measure. However, maintenance of an effective pneumothorax (one which does not close cavities) beyond a trial period of from 6 to 8 weeks is a questionable practice unless adjuvant measures, such as open pneumolysis, phrenic paralysis, and pneumopneumothorax, are used. Advanced endobronchial tuberculosis of the major bronchi is a contraindication to artificial pneumothorax as the partially obstructed bronchus may become completely obstructed after pneumothorax collapse. In the case of tension cavities, pneumothorax often results in an enlargement of the cavity.

With the increasing safety of resection, thoracoplasty will probably be used more and more for early thin-walled cavities of the upper lobe. The effectiveness of phrenic nerve operations is difficult to evaluate.

Drainage operations (open cavernostomy and closed catheter drainage) are occasionally performed. Cav-

ernostomy has been repeatedly tried and discarded. It is sometimes done as a preliminary operation to thoracoplasty when the patient has a tension cavity or a very large cavity which may resist simple thoracoplastic collapse. Monaldi's closed cavity drainage is used sometimes in the treatment of very large and tension cavities and as an adjuvant to thoracoplasty in these types of cases.

The most classical indication for resection in pulmonary tuberculosis is severe bronchial stenosis with retention of secretions distal to it. Other indications are tuberculoma, check valve or tension cavities, very large cavities, hilar cavities, lower lobe cavities in which pneumothorax is ineffective, bronchiectasis residual to tuberculous infection with persistent positive sputum, cavities which have resisted anatomically adequate collapse therapy (usually thoracoplasty), bronchopleural fistula with mixed tuberculous empyema, and a destroyed lung.

The contraindications to operation in bronchogenic carcinoma are metastases to distant parts or to a nearby part which cannot be resected. Marked distension of the neck veins, indicative of serious superior vena cava obstruction, and the presence of a very copious purulent expectoration in cases which are likely to be inoperable from other evidence, are almost contraindications to even a simple exploration.

Whenever feasible pneumonectomy is the operation of choice for bronchogenic carcinoma. When it is impossible to obtain a cure because of intrathoracic extension, and yet it is possible to remove the primary lesion by lobectomy or pneumonectomy, palliative resection is a valuable measure. Surely the removal of an obstructed, suppurating lung along with the primary lesion cannot but improve the patient's general condition. Following pneumonectomy thoracoplasty is done when the patient appears to have been cured, and when he is vigorous enough to tolerate the procedure without risk.

SAMUEL KAHN, M.D.

HEART AND PERICARDIUM

Physiological Studies in Congenital Heart Disease: Measurements of the Circulation in 5 Selected Cases. L. D. VANDAM, R. J. BING, and F. D. GRAY, JR. *Bull Johns Hopkins Hosp* 947: 8, 92.

The authors chose 5 selected cases to illustrate the diagnostic value of physiological studies when applied to a variety of clinical problems dealing with congenital heart disease. The preceding articles of this series have been concerned with procedures employed and studies of circulatory measurements of the tetralogy of Fallot and of Eisenmenger's complex. Most of the data were obtained by applying the Fick principle. Blood gas values substituted in the Fick equation were obtained by catheterization of the heart chambers and great vessels by arterial puncture, and by analysis of the respiratory gases.

At postmortem examination the first patient showed a heart which functioned as though it had

a single auricle, because of a patent foramen ovale and a 3 cm. articular septal defect. The left ventricle gave rise to the pulmonary artery and most of the aorta since it straddled a 4 cm. defect in the interventricular septum. The blood flows from the pulmonary capillaries and pulmonary artery were reduced to 1,480 and 1,900 c.c. respectively and of these amounts slightly more than half was venous blood, the predominating direction of the intracardiac shunt was right to left and the peripheral blood oxygen saturation was 69 per cent. The oxygen content of the blood from the ventricles corresponded closely to that of the peripheral blood, which suggested a single ventricular compartment.

The second patient presented the tetralogy of Fallot. The pulmonary capillary blood flow was reduced to 3,390 c.c. The right ventricular blood was found to be 3.6 volumes per cent higher in oxygen content than the blood from the auricle. The pulmonary artery and effective pulmonary blood flows were 1,500 c.c. and 1,935 c.c. respectively. The collateral blood flow to the lungs was 800 c.c. and the intracardiac shunt directed from right to left was 200 c.c. The systemic blood flow was 1,850 c.c.

The third patient had a large patent ductus. The data accumulated before operation indicated a left to right extracardiac shunt. However there was some indication of right to left shunting in the results obtained with peripheral oxygen saturation tests.

The fourth patient had a patent foramen ovale and stenosis of the pulmonary valve. Results of catheterization and exercise tests showed evidence of a reduction in the pulmonary artery blood flow, a reduction in the effective blood flow to the lungs, and the probable presence of an intracardiac shunt. Elevated intraventricular pressure on the right side and a reduction in pulmonary artery pressure indicated pulmonary stenosis.

The fifth patient had a very small pulmonary artery with a large collateral circulation to the lungs. In spite of fluoroscopic findings of a prominent pulmonary conus, increased lung markings, and pulsations in the lung fields, a diagnosis of pulmonary stenosis could be made following performance of exercise tests and catheterization of the right ventricle.

W. FOSTER MONTGOMERY, M.D.

Wounds of the Heart; 9 Cases (Ferimentos do coração; comentários sobre 9 casos). R. FERREIRA SANTOS, A. DIAS DE ALMEIDA, and F. C. SILVA TELLES. *Rev Hosp Clin*, 947: 2, 95.

The authors review their experience derived from managing 9 cases of cardiac wounds seen in a 3 year period at the Serviço de Pronto Socorro do Hospital das Clínicas da Faculdade de Medicina da Universidade de São Paulo, Brazil.

The symptomatology and clinical picture are reviewed in some detail, with emphasis on the two principal types of wounds: (1) that produced by cardiac tomopuncture and (2) that produced by hemorrhage (hemothorax or external bleeding). An injury occurring within the danger zone of Ziegler (a quadri-

lateral space between the right parasternal and left anterior axillary lines and the angle of Louis above to the level of the tenth rib below) should be carefully watched for evidence of cardiac involvement.

The authors favor surgical intervention instead of more conservative management because of the delayed complications which occur in apparently controlled cases. The operative approach they used was either a median sternum-splitting incision or a thoracotomy at the left fifth intercostal space.

There were 5 deaths among the 9 cases. Seven patients were operated upon with 3 deaths. The 9 case histories are given in fairly ample detail.

Numerous diagrams, photographs and semidia phragmatic charts illustrate the text. Thirty-six bibliographical references are appended.

HERMAN T. LANGSTON, M.D.

ESOPHAGUS AND MEDIASTINUM

Esophageal Varices. HERMAN J. MOERSCH, *J. Am. M. Ass.*, 1947 135 754.

The results of treatment in 22 cases of esophageal varices in which gastrointestinal hemorrhages occurred are reported. In these cases the patients were treated by the injection of a sclerosing solution into the varices through the esophagoscope. At the time the study was made 12 of the patients had had no further bleeding after treatment, all 12 had gone longer than 3 years without bleeding, and 8 had gone more than 4 years without bleeding.

Patients in whom satisfactory results were not obtained by injection of a sclerosing solution invariably were found to have varices in the cardiac end of the stomach as well as in the esophagus, which was not true in the successfully treated cases.

Röntgenologic examination is of great value in the diagnosis of esophageal varices but is not infallible. In doubtful cases esophagoscopy should be employed.

In cases of varices in which the cardiac end of the stomach as well as the esophagus is involved some form of treatment other than that of injection of a sclerosing solution, such as portal caval anastomosis or resection of the cardiac end of the stomach and lower end of the esophagus, should be considered. The authors thought that such an alternate form of treatment eventually may even become the procedure of choice in uncomplicated cases of esophageal varices.

Clinical and Radiologic Features of Lymphatic Metastases in Carcinoma of the Thoracic Esophagus (Estudio clínico y radiológico sobre las adenopatías neoplásicas del cáncer del esófago torácico) J. HORACIO REZANO, *Boletín Soc. cir. Uruguay*, 1947 18 101.

Radical surgery for cancer has two objectives: extirpation of the tumor and removal of its metastatic field. In the case of cancer of the esophagus, the accomplishment of these objectives is difficult because of two anatomical characteristics of this organ: (1) a

Fig. 1. (Rezano) Metastatic field of esophageal carcinoma which was found to be involved most frequently: (1) the jugular chain, (2) the node situated at the origin of the right subclavian artery, (3) the right paratracheal node, (4) the subcortical or tracheobronchial node, (5) the right posterior hilar node, (6) the paraesophageal node (Vesalius), (7) the nodes along the cardia, and (8) the nodes of the left gastric group.

poor supply of blood, and (2) a rich lymphatic bed. The latter circumstance permits a varied and complicated metastatic pattern because metastases do not necessarily occur in segmental fashion but may occur first at some rather distant point. The demonstration in patients of the presence of metastatic involvement can be undertaken by three means: clinical examination, radiologic examination, and direct examination at surgery.

The physical examination is of practical value only for metastatic involvement occurring in groups of nodes accessible to palpation, such as the supraclavicular, carotid, or axillary, and presupposes of course gross enlargement of the nodes. As a general rule, a cancer of the esophagus (except in the cervical and cervicothoracic portions) which is accompanied by palpable metastatic lymphadenopathy is exceptional and usually signifies a very advanced stage of the disease. Among some 500 cases of carcinoma of the esophagus, there were only 8 which presented palpable lymphadenopathy.

The search for metastatic lymphadenopathy located intrathoracically was done by means of roentgenography, but it can be said that for practical pur-

poses metastatic lymph adenopathy in this region is not recognizable radiologically even though the nodes may have attained some size. They become demonstrable only if their density is increased by some such process as calcification. Using several illustrative roentgenograms, the author demonstrates this point, and calls attention to the fact that by positioning the patient, one may superimpose pulmonary or other intrathoracic shadows on the mediastinum and lead to the erroneous impression that metastatic involvement is present. This is obviated by the proper interpretation of films in more than one position.

Experience with many cases of carcinoma of the esophagus subjected to surgical exploration permits certain conclusions concerning the demonstration and importance of metastatic involvement.

The relationship of metastatic involvement to the size of the primary tumor is not a direct one often being, in inverse ratio. It is the author's belief that the extensiveness of metastatic involvement bears a direct relationship to the duration of symptoms rather than to the size of the original lesion.

In lesions occurring below the level of the tracheal coryna, the presence of involved paroesophageal nodes (nodes of Vesalini) is constant.

The importance of considering the removal of the metastatic field is emphasized by pointing out that this may be a determining factor in selecting a right or left surgical approach, because tumors located below the tracheal bifurcation involve predominantly the subcorynal and paroesophageal nodes and the nodes along the left gastric artery whereas tumors above this level involve nodes at the tracheal coryna, the paratracheal fossa and all along the right subclavian artery where the recurrent laryngeal nerve circles it. Thus, the lower tumors seem manageable from the left side, whereas the higher tumors may indicate an approach from the right side.

The presence or absence of metastatic nodes may finally determine whether a resection is justified, although it seems that the author is willing to perform palliative resection, leaving metastatic nodes, if the re-establishment of gastrointestinal continuity is possible.

HIRSH T. LAMOSTON, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Massive Congenital Umbilical Hernia Amniotic Hernia (Las grandes hernias Umbilicales congénitas—hernias amnióticas) JOSÉ M. JORGE. *Bol Acad argent cir.*, 1947 31 705

When a massive umbilical or epigastric hernia occurs in the newborn the possibility of eventration transcends the importance of the hernia. Immediate operation is indicated before malnutrition, erosion, infection or other complications can intervene. The principal consideration should concern the volume of the eviscerated structures and whether or not the abdominal cavity is sufficient to contain the displaced viscera. The case history of a 3 month old child with a gigantic congenital embryonic umbilicoepigastric hernia containing the intestines, stomach and liver is described (Fig. 1).

Röntgenograms revealed the dangers of replacement of the organs in the abdominal cavity. Pneumoperitoneal injection facilitated abdominal distention, replacement, and retention of viscera in their normal relationship. The overlying skin was not sacrificed but permitted to remain intact for possible future demand commensurate with the growth of the child.

The infant mortality in these large hernias was considered extremely high, the cause being shock or embarrassment of the abdominal viscera when confined to an abdominal area too small to hold them properly.

STEPHEN A. ZIEGLER, M.D.

The Importance of the Conformation of the Pelvis in the Genesis of Inguinal Hernia (L'importanza della conformazione del bacino nella genesi dell'ernia inguinale) CARLO PIANA. *Arch ital chir* 1947 69 309.

Pelvic measurements were taken of 500 patients with inguinal hernia at the Bassini Institute, Milan. Of these patients, 453 were male and 46 female. A review of the literature pertaining to the relationship between inguinal hernia and pelvic measurements is presented. The author does not agree with Harris and White who concluded that the type of inguinal hernia is related to the length of the inguinal ligament.

On the basis of these measurements the author makes the following conclusions:

1. There exists in individuals with inguinal hernia a dysmorphism of the pelvis which can be defined as bacino emiloso hernial pelvis.

2. With regard to the single components which make up this dysmorphism it is noted that:

a. The inguinal ligament is longer than normal.
b. The length of the ligament varies in minimal measurement with the type of hernia, direct or indirect. Therefore a differential clinical diagnosis can not be made of the different types of her-

Fig. 1 (Jorge)

nia on the basis of the length of the inguinal ligament.

c. The large pelvis presents an enlargement in all diameters in males with inguinal hernia.

d. In females however the enlargement is minimal in certain diameters, whereas in other diameters it is less than normal (sacropubic, bitrochanteric). In the male the hernial pelvis tends to be larger than normal, whereas in the female it tends to be smaller than normal. All measurements taken into consideration it can be said that the female hernial pelvis has a tendency to approach the form of that of the male.

e. The height of the pelvis measured from the inferior margin of the pubis to the midpoint of the bisiliac line is larger in individuals with inguinal hernia than in normal individuals.

3. The pelvic dysmorphism modifies the morphologic aspect of the inguinal canal and consequently its valvular action. Bassini attached great importance to this fact as he believed that it created a condition favorable to the development of inguinal hernia.

LUCIAN J. PROSDUTI, M.D.

Streptomycin in Surgical Infections. Peritonitis.

EDWIN J. PUTASKE, SAM F. SEELEY and CHARLES S. MATTHEWS. *Surgery* 1947 22 589

Sixty three patients with peritonitis of varying etiology of whom 5 died received adjuvant streptomycin therapy alone or in combination with penicillin. Sulfadiazine was added in a few cases. The beneficial effects of early streptomycin therapy in early spreading peritonitis closely paralleled those

observed in cases in which large doses of penicillin were given. Streptomycin did not seem to be of particular value in the treatment of localized peritoneal suppuration.

On the basis of these preliminary studies, it is apparent that streptomycin is not a panacea, but has a valuable place in the treatment of peritonitis. Used alone, it is especially effective in spreading and localizing types of infection without a palpable mass. Used in conjunction with penicillin, it is effective in many patients who fail to respond to penicillin alone or to penicillin combined with sulfonamides.

SAMUEL KAHN, M.D.

Tumors of the Mesentery (Tumori del mesentere) C. SIMONETTI. *Ann. Ital. chir.* 947 24 333

The article is concerned with roentgenologic signs which assist in making a diagnosis of mesenteric tumors.

The mobility of the tumors with respiration and upon manipulation is considered of great importance.

Another criterion is the ability to demonstrate air between the mass and the posterior wall by means of pneumoperitoneum. In this way the mass is surrounded by air on all sides except where it is attached to the posterior wall. Theoretically however a retroperitoneal mass which grows and forms a pedicle will give the same signs. Practically however it is difficult to isolate the mass completely from the posterior parietal peritoneum by gas.

The differential diagnosis is concerned with ovarian cysts, cysts of the large ligament, pancreas, liver and spleen, movable kidney inflammatory tumefaction, and neoplastic tumors of the retroperitoneal tissue.

Three case reports are given, in 2 of which the diagnosis was confirmed by operation. One tumor was a lymphosarcoma and the second represented a metastatic growth from prostatic cancer. The tumor not subjected to surgery was considered to be a lymphosarcoma which was treated with x rays. The mass became smaller but the patient's condition continued to get worse and death occurred a month later.

LOUIS J. F. OTTO, M.D.

GASTROINTESTINAL TRACT

Section of the Vagus Nerve to the Stomach in the Treatment of Peptic Ulcer. LESTER R. DRAGSTEDT, PAUL V. HARPER, JR., E. BRUCE TOYKE, and EDWARD R. WOODWARD. *Ann. Surg.* 1947 126 687

During the period from January 18, 1943 to March 1, 1947 division or resection of the vagus nerves to the stomach as a method of treatment was employed in the University of Chicago Clinics in 23 patients with various types of peptic ulcer. One patient died of aspiration bronchopneumonia, and there have been no deaths in the last 150 vagotomies performed. Adverse reflex effects that might be ascribed to stimulation of the vagus nerves have not been seen. The clinical results of the operation have been excellent and have given the authors the im-

pression that a benign peptic ulcer may be regularly expected to heal if all the vagus fibers to the stomach are divided.

This is best accomplished by exposure of these nerves along the lower esophagus by either a transabdominal or a transthoracic approach. The transabdominal operation has the significant advantage that it makes possible inspection and palpation of the lesion and the performance of a gastroenterostomy should cicatricial obstruction at the pylorus be present. Gastric vagotomy abolishes the nervous phase of gastric secretion and decreases very markedly the total amount of gastric juice produced. These effects appear to be permanent. Evidence of regeneration of the secretory fibers in the vagus nerves has not been observed even in the patients operated upon 4 years ago. These findings suggest that regeneration of the divided vagus fibers will not prove to be a troublesome feature of this type of operation.

Complications and undesirable sequelae that have been encountered are intercostal pain or neuralgia, pleural effusion, pulmonary atelectasis, delayed emptying of the stomach, and diarrhea. For the most part these complications have been mild and self limited. Careful attention to postoperative care reduces the incidence and severity of most of them. Persistence of ulcer symptoms has been observed in 5 patients, and in these physiologic tests have indicated that not all the vagus fibers were divided. In 2 of these patients a second operation was performed and a residual vagus fiber was discovered and divided.

These findings suggest that to be effective in abolishing the nervous phase of gastric secretion and causing the healing of benign peptic ulcers, removal of the vagus innervation of the stomach must be complete. It is probable that the poor results secured by the early workers in this field were due to the fact that attempts were made to section the vagus nerves in operations directed at the stomach instead of at the esophagus and therefore they were in all probability incomplete. The necessity of repeated physiologic tests to determine residual vagal innervation of the gastric glands is clear and should be emphasized.

JOSEPH GASTRICK, M.D.

A Contribution to the Study of Gastric Abscess (Contributo allo studio dell'asscesso gastrico) DOMENICO MARTINI. *Gior. Ital. chir.* 947 3 54

Suppurative processes in the stomach are rare and for the most part are represented by operative surprises or autopsy reports. Only in rare cases has the diagnosis been made before operation. The condition was first reported by Galen (1037). According to the most recent statistics there have been about 35 cases (Sgildiani 941).

The male is more often afflicted, from 71 to 83 per cent, and while both young and old may be affected this condition is most commonly seen between the ages of 30 and 50 years.

Many classifications have been presented, but all have been discarded for the more simple diffuse and

circumscribed suppurative gastritis. The most common organism is the pyogenic *Streptococcus* which is present in from 70 to 78 per cent of the cases. It may be present alone or in combination with other bacteria: the *Bacillus coli* and proteus, the *Diplococcus* and the *Staphylococcus*. Very infrequently the *Staphylococcus* or *Diplococcus* have been found in pure culture, and rarely the *Bacillus coli* and *Bacillus anthracis*.

The pathogenesis is said to be dependent upon the presence of three factors: (1) diminution of the gastric acidity, (2) a traumatic lesion and (3) virulent streptococci. As one gets away from these factors it becomes increasingly more difficult to produce inflammatory lesions in the gastric wall. The juxtapyloric area is the most frequent site. The macroscopic appearance is that of irregularity and a consistency sometimes fibrous other times moist. The serosa is hyperemic and edematous with lymphangitis and a deposition of fibrin on the affected zone.

The symptoms of gastric suppuration are so complex as to make the diagnosis difficult and at times impossible. Generally there is a picture of acute pain fever and accentuated leucocytosis. It may simulate a perforated peptic ulcer or empyema of the gall bladder.

The condition may be cured by emptying of the pus into the stomach spontaneously but more often there is a spread with consequent purulent peritonitis, localized or diffuse.

The treatment is surgical and depends upon the nature of the lesion. In the presence of a diffuse phlegmonous form the prognosis is poor and only drainage is recommended. If the lesion is localized, different methods have been used, varying from simple drainage, gastrostomy gastroenterostomy and gastric resection.

A case report in a 24 year old male is reported. He was operated upon for a perforated duodenal ulcer. When the abdomen was opened multiple adhesions were found and were liberated. The abscess was found in the gastric wall. A Polya type of gastric resection was performed and drainage with gauze and a rubber tube was instituted. A subtotal closure of the abdominal wall was used and the wound was closed by second intention. The patient was discharged as cured in 42 days.

LUCIAN J. FROMDUTT, M.D.

Benign Tumors of the Stomach. *National Statistics (Tumores benignos del estómago estadística nacional)* ALEXANDRO J. PAVLOVSKY and DANIEL J. JOLY. *Revista med. argent.* 1947 34 1168.

The authors give the incidence of gastroduodenal polyps in Argentina, comparing their findings with those of previous studies made abroad. They found 41 polyps at operation. Of these 35 were benign and located in the stomach; 1 was benign and located in the duodenum; 1 benign gastric polyp coexisted with a gastric cancer and 4 gastric polyps were regionally benign but had become malignant. Of the benign polyps of the stomach

13, or 37.1 per cent were correctly diagnosed before operation and 22 or 69.0 per cent, were mistaken for other conditions. The most frequent incorrect diagnosis was gastric cancer.

WILLIAM E. RICKETTS, M.D.

Carcinoid Tumors of the Stomach (I carcinoidi dello stomaco) ACHILLE ELIO GALLIMARO. *Arch. ital. chir.* 1947 69 239.

The author reports a case of carcinoid tumor of the stomach which represents the fourteenth reported case in the world's literature, the second in the Italian literature and the fifth to come to the operating table.

After having discussed the differential diagnosis from the histologic point of view keeping in mind the data reported in the previous cases, the author believes that aside from the eventual gastroscopic reports there is no other sign which can lead to the diagnosis. His preoperative diagnosis was duodenal ulcer.

As to treatment, he recommends ample gastric resection inasmuch as carcinoids, although usually benign, may undergo malignant degeneration at any time.

As for the histogenesis, the author believes that the theory of embryonal malformation is the only one which can justify the great rarity of these tumors in the gastric region, and explain the frequent absence of the affinity for chromaffin and silver stains on the part of the neoplastic cellular elements. Even in the absence of specific impregnations, the certain diagnosis of carcinoid is rendered possible by other characteristics of major constancy. Among these are the submucosal position of the tumor, its entire delimitation, the more or less abundant stroma rich in elastic fibers and smooth muscle, and the frequent variable aspect of the cells which are regularly benign.

LUCIAN J. FROMDUTT, M.D.

Cancer of the Stomach (from a Radiologist's Point of View) J. L. A. GROUT. *Brit. J. Radiol.* 1947 20 491.

Perhaps the most disturbing feature of carcinoma of the stomach is the short duration of the symptoms, even in cases in which the growth in the stomach is extensive and often inoperable. Hence the radiologist is faced with the fact that a large percentage of patients with suspected carcinoma of the stomach are referred to him when the disease is already far advanced. The radiologist is often left with the thankless task of confirming the presence of a new growth already diagnosed by the physician or surgeon.

The author presents a number of interesting case histories and radiographs to illustrate the extensive lesions which may be present in a person with symptoms of very short duration. The role of gastroscopy as an aid to the diagnosis of carcinoma of the stomach is emphasized. Mistakes made in radiology can many times be corrected by a good gastroscopic examination.

It is emphasized that radiography is not the means of making a final diagnosis, but it should play an important part in the evidence collected before a final opinion or judgment as to the nature of the disease is given. The clinician must realize that the radiologist is not a robot and his opinions are not necessarily final nor closed to contradiction. If the clinician would avoid the use of the words "the X ray shows" and use instead "the radiologist says," a better understanding of the two points of view would prevail and a more practicable and useful approach could be made to the problems of diagnosis and research.

HAROLD LAUFMAN, M.D.

Gastrosocopy in the Diagnosis of Gastric Cancer H. W. ROOZEK. *Brit J Radiol* 947 20 505

Gastrosocopy should logically follow the x ray examination in the routine investigation of dyspepsia, and in a case suspected of carcinoma. It is particularly important that this routine should be adhered to for there are certain important contraindications to gastrosocopy in the presence of carcinoma which are diagnosable from the roentgenogram. If the x-ray examination has already demonstrated an advanced carcinoma, gastrosocopy will not be of any further help in such a case there is risk of rupture of the growth or perforation with the instrument. Another contraindication to gastrosocopy even when a carcinoma is suspected is gross deformity in the course of the esophagus, due either to spinal curvature or to intrathoracic displacement. Atrophy of the mucosa of the esophagus occasionally accompanies carcinoma of the stomach, although this does not constitute an absolute contraindication to the use of the instrument however it does call for the greatest care in its passage.

Gastrosocopy is indicated in a case clinically suspected of being carcinoma when the roentgenogram has revealed either no lesion or a lesion of obscure nature. It is further indicated when an ulcer appears to be innocent on the screen, but carcinoma is suspected clinically.

There are 4 manifestations of carcinoma of the stomach as seen with the gastroscope

1. Projection of neoplastic material into the lumen. The cauliflower mass as a rule is seen easily the multicolored necrotic surface appearing very different from the surrounding gastric mucosa. The surface of such a neoplasm is usually covered with blood, mucus, and slough.

2. Ulceration of the growth. Ulcers vary greatly in size and shape, but the following characteristics are usually retained a raised irregular edge, irregular in color and contour a sloughing floor containing blood and necrotic tissue irregularity or nodularity of the surrounding mucosa and raising of the whole ulcer above the surrounding mucosa. Ulcerated carcinomas constitute the commonest type of gastric growth.

3. Fibrous ulcer with malignant change—the ulcer cancer. The gastrosocopic characteristics of such a lesion are irregular hyperemia of the ulcer

region or of the surrounding mucosa an irregularity in the outline of the ulcer especially a breaking up of a part of the smooth margin by an irregular nodularity the appearance in the floor of the ulcer of blood clot or necrotic tissue instead of the comparatively smooth greenish gray although seen in innocent ulcers infiltration of the surrounding mucosa with carcinoma. This type of lesion has gradations from an innocent looking ulcer to the ulcer which is obviously the starting point of a widespread carcinomatous infiltration. These cases are the ones which tax the diagnostic skill of the gastroscopist to the utmost.

4. Submucous infiltration as seen in leather bottle stomach. The affected walls are devoid of folds or the normal mammillation and are composed of completely irregular nodules which may be pale in places and hemorrhagic in others, with a considerable excess of dirty mucus on the surface. The affected mucosa is rigid and changes little if at all, on inflation while the unaffected parts distend normally. Superficial ulcers are common in this type.

An ulcer with a suspicion of malignancy at the angulus may justifiably be left for a decision at a re-examination in 14 days. A similar ulcer seen on the greater curvature should be operated on without delay.

Since the outcome of gastric carcinoma remains so gloomy, the author suggests a careful but enthusiastic effort in the search for precancerous lesions. He considers three varieties of lesions in this category (1) polype and adenomas (2) chronic gastric ulcer (3a) gastritis with atrophy and (3b) gastritis without atrophy.

Associated with carcinoma of the stomach one frequently finds that the mucosa contains an undue number of very fine blood vessels finer than the usual submucosal veins. These blood vessels, the author believes, lie in the mucosa itself and he has therefore called them intramucosal vessels. He finds these so frequently associated with carcinoma that he believes they might be considered precancerous lesions although these vessels are sometimes seen in patients not suffering from carcinoma.

HAROLD LAUFMAN, M.D.

Cancer of the Stomach: Some Pathologic Considerations. M. J. STEWART *Brit J Radiol*, 947 20 505.

From the pathologist's point of view the problem of diagnosing an ulcer cancer of the stomach remains an exceedingly difficult one. The chief histological difficulty is in determining whether there is sufficient evidence to say that a simple chronic ulcer has certainly preceded the onset of epithelial malignancy. The bone of contention among pathologists rests on the following question. Can peptic ulceration occurring in a primary carcinoma so destroy at least the central part of the growth with its replacement by simple chronic inflammatory tissue as to render it, in that part at least indistinguishable from a simple lesion? Alternatively can peptic ulceration, commencing in a primary cancer spread from the growth

onto the adjacent healthy (or at least non neoplastic) stomach wall and produce a like result?

There are cases in which the pathologist hesitates to give an opinion unless buttressed and fortified by clinical evidence. In nearly all the cases which the author includes in his series of ulcer cancers there is a gastric history of 2 years or longer. However there are exceptions to this statement since in many patients there was an interval of freedom from symptomatic ulcers or ulcers and gastric carcinoma.

The range of acidity in the ulcer cancer approximates that of simple chronic ulcer much more closely than that of primary carcinoma. Twelve of 58 patients with primary cancer secreted a juice of normal or brightened acidity without anatomic simulation of ulcer cancer.

From the prognostic point of view, the author's impression is that the outlook in scirrhus cancer is unfavorable as compared with encephaloid. Even in tumors of considerable size if these are of the polypoid or fungating encephaloid type and provided the surgeon has been able to achieve an apparent removal of the whole growth with a reasonable margin of apparently healthy tissue the prognosis is incomparably better than in scirrhus cancers how ever small and however recent they appear to be.

Admittedly scirrhus cancer is of slow evolution but the chances are that by the time the case comes to operation lymphatic permeation has already extended far beyond the confines both of the stomach itself and of the regional lymphatics ordinarily removed in the operation of gastrectomy. In patients with ulcerating cancers of encephaloid type are likely to prove much more rapidly fatal than those of the scirrhus type. No doubt, the better prognosis of the encephaloid cancer after operation is in part accounted for by its earlier diagnosis and consequent earlier treatment. Widespread suppuration is frequent in the softer and more massive types of gastric cancer and may lead to peritonitis after surgery.

HAROLD LAUTMAN, M.D.

The Surgical Aspect of Carcinoma of the Stomach

HARMON TAYLOR *Brit J Radiol* 1947 30 507

Although the primary diagnosis of carcinoma of the stomach rests upon radiology and gastroscopy, the question of operability can be finally decided only after the surgeon has opened the abdomen. When distant metastasis in the liver or peritoneum especially in the pelvis or local extension of the growth into the posterior abdominal wall or diaphragm indicates a fatal outcome, some surgeons will nevertheless carry out a palliative gastrectomy for the relief of symptoms. The author does not agree with this point of view. When widespread metastases are already established the primary growth is generally not responsible for the main symptoms or the fatal outcome and in the absence of obstruction there is little to be gained by removing it. Gastrectomy is the simplest and therefore the best

means of dealing with obstruction of the pylorus in the inoperable case.

Individual operative mortality statistics are misleading and can be interpreted only in relation to the proportion of operations in which the growth was removed and the proportion of patients who escape recurrence of the lesion in subsequent years. Much depends upon the skill and experience of the surgeon and upon his determination to take serious risks if thereby he can give the patient a chance of cure. If there are no distant metastases the author believes that every risk should be taken to resect the growth. The surgeon should be prepared to remove the whole stomach together with omentum, the spleen, the transverse colon and the tail or body of the pancreas if these are involved in the lesion. It may be supposed that even successful removal of a growth so extensive must surely be followed by recurrence but this is not necessarily true. Among 38 patients subjected to radical removal of gastric carcinoma in the author's series there were 17 in whom one or more of the viscera were removed with the stomach. Of these 7 died as a result of the operation of the 10 survivors 8 are still alive and well from 1 to 4 years afterward.

In the last decade many helpful advances have come to the aid of the surgeon. One need only mention penicillin, curare, the endotracheal tube and the refinements of blood transfusion. Although the risk is in each case far reduced by these means, the mortality rate for operations for carcinoma of the stomach remains high because the surgeon is encouraged to undertake still more extensive removal of tissue when necessary.

In recent years growths of the cardia have become ever more removable. The growth is exposed through the left side of the chest and the left dome of the diaphragm and the resection accomplished with which he never successfully earned out but which now has become practicable.

HAROLD LAUTMAN, M.D.

Late Effects of Total Gastrectomy in Man

M. MACDONALD, FRANK J. MOELLINGER, and HELEN W. BELZING *J. England J. Med.* 1947 337: 837

Studies on patients who have survived total gastrectomy for 3 years or more are few and contradictory results are reported.

Studies have been made of intestinal motor function, intestinal absorption, pancreatic function and the blood picture in 3 patients who have survived total gastrectomy for 3, 5 and 10 years respectively. The first patient who survived total gastrectomy was studied 50 years ago and it was noted with surprise that she regained her appetite. Since then others have observed that the stomach is not necessary for this sensation. All patients have a normal desire for food and develop hunger. None of the patients have dysphagia or symptoms suggesting the dumping syndrome. The weight has never regained the levels existing before illness.

Fluoroscopic and radiologic examination revealed a normal esophagus and a patent, well functioning esophagojejunal anastomosis.

Until recently, the patient of Zikoff was considered the longest survivor after total gastrectomy for carcinoma, since Finney and Reinhold reported her alive 4 years and 8 months after operation. Zikoff's article, however, is an early postoperative report which does not contain any information concerning subsequent survival. Attention is directed to a much overlooked reference to the Lichtenhan lecture of 1906 by H. J. Paterson. In this monograph he quotes a personal communication from MacDonald of San Francisco to the effect that the patients of Brooks Brigham and of MacDonald were alive and well 8 and 7 years after their operations. Incidentally the operations were the second and third successful total gastrectomies reported in the literature. One of the patients studied is alive and well 10½ years post-operatively whereas the patient described by Poole and Foster is still alive and well 20 years after the complete removal of the stomach for a nonmalignant condition. These 3 cases appear to represent the longest known survivals after total gastrectomy for malignant and nonmalignant tumors, respectively.

Studies on 2 patients who had survived total gastrectomy 10 and 3 years, respectively and on 1 who had survived total gastrectomy, splenectomy, and partial pancreatectomy 5 years revealed the clinical condition of the patients with total gastrectomy alone to be excellent. Considerable dilatation of the jejunum near the esophagojejunal anastomosis was demonstrated by roentgenologic and kymographic methods in 1 case. In both cases, the pancreatic enzymes were normal and fat absorption on a low fat intake was not significantly impaired. Vitamin A tolerance curves showed an apparently delayed but otherwise normal absorption of the vitamin. Glucose tolerance tests disclosed an early and marked but transient hyperglycemia.

The patient with total gastrectomy, splenectomy and partial pancreatectomy experienced difficulty in maintaining weight. Dilatation of the jejunum was present. The pancreatic enzymes were deficient, fat absorption was impaired and the vitamin A tolerance curve was flat. The glucose tolerance curve showed a hyperglycemia, which was sustained.

Blood studies demonstrated that 2 of the 3 patients developed a macrocytic, hyperchromic anemia 3 and 5 years, respectively after operation. The third had received prophylactic liver treatment. A review of the literature revealed a high incidence of macrocytic, hyperchromic anemia in patients surviving total gastrectomy for 3 or more years.

The evidence appears to support the statement that an anemia morphologically similar to Addisonian pernicious anemia will develop after total gastrectomy if the patient survives long enough. Whether the anemia is truly Addisonian or whether it is another form of macrocytic anemia requires further study. In the past most patients developing macrocytic anemia after total gastrectomy have

been incompletely studied, for the effects of dietary deficiency have not been excluded—liver and iron have been administered indiscriminately—and special studies like reticulocyte counts and bone marrow examinations have been few. Only if macrocytic anemia that follows total gastrectomy is carefully investigated by the methods used by Meyer *et al.* can its relation to Addisonian pernicious anemia be clarified.

HARRY W. FOX, M.D.

The Surgical Management of Gastrojejunal Colic Fistulas. ROBERT F. BARKER and JOHN L. MATTEN. *Surgery* 94:7:1657

A series of 6 cases of gastrojejunal colic fistula is reported. The authors consider the multistage method of treatment with the use of a preliminary colostomy as described by Pfeiffer the most logical from a surgical standpoint. A historical review of the surgical attacks on gastrojejunal colic fistula is given.

The method of Pfeiffer is preferred by the authors because (1) there is cessation of diarrhea with a return of the patient to excellent physical status and hence reduction of the general risks of surgical intervention (2) there is subsidence of the inflammatory reaction of adjacent tissues and the jejunal ulceration thus reducing the risk of inflammatory complications in the surgical correction of the fistula, (3) there is freedom from contamination at operation and later protection of suture lines in the repaired colon which abolishes the danger of leakage and (4) the operation is technically simple.

In the second stage of the procedure, which follows the colostomy from 6 to 10 weeks, the authors prefer a disconnection of the fistula followed by a subtotal gastric resection to the "simple restoration of gastro-intestinal continuity. Simple closure of the fistula combined with infradiaphragmatic partial vagotomy although not reported, is suggested for possible clinical trial.

W. FOSTER MONROE, M.D.

On Subcutaneous Injuries of the Intestine, with Special Reference to the So-Called Secondary Injuries. E. TIMMONS and J. ANTONIEN. *Ann. chir. exp. med.*, 1947 35:96.

In the period from 1935 to 1945 there were 32 cases of injuries to the intestine secondary to contusion of the abdomen in the three largest hospitals of Helsinki. The theory of mechanism for intestinal rupture without injury to the abdominal wall has been explained as one of three main types: (1) the intestine may be crushed (2) the intestine may be torn and (3) the intestine may be burst. Among the 32 cases there were 26 injuries to the small intestine, 5 to the large intestine, and 1 in both the small and large intestine. The prognosis is dependent upon the severity of the trauma, upon the state of shock caused by the trauma, and how soon after the trauma operation is performed. In the material reported there were 15 fatal cases. Three patients died of other associated injuries.

The only possible treatment is, of course, operative. It is more important to treat the shock after

trauma than to institute hasty operation. Adequate treatment of the shock requires a period of calm waiting which is far more essential than hasty operation immediately after trauma.

SAMUEL J. FODERSON, M.D.

Carcinoma of the Ampulla of Vater JOHN MORLEY
Brit. J. Surg., 1947 35 146

Morley described his experience with 6 cases of carcinoma of the ampulla of Vater. Treatment consisted of a radical two stage operation with ligation of the pancreatic duct. Four patients died. 1 was ill from ascending cholangitis some 7 months after operation and the sixth patient was well 11 months after the second stage of the operation.

The author discussed the merits of the one stage and the two stage operations. He does not approve of Whipple's method of restoration of the flow of bile, preferring a cholecystogastrostomy to the anastomosis of the divided common bile duct with the jejunum, nor of Whipple's policy of implanting the pancreatic ducts into the jejunum. Morley believes that ligation of the pancreatic duct is a safer procedure than anastomosis of this duct with the jejunum. This policy is based on the author's experience with 5 of his 6 patients who gained weight on an ordinary diet without the use of pancreatic extract. No serious failure of fat absorption was observed. Apparently the individual's nutrition does not suffer by withholding the powerful digestive juices—trypsin, lipase, and amylase—through the ligation of the pancreatic duct. Morley's sixth patient, however, developed an acute fatal pancreatitis which could be ascribed to the ligation of the pancreatic duct.

The article is concluded with the report of a questionable case of apparent spontaneous cure of ampullary carcinoma.

ROBERT TURELL, M.D.

Symptoms Due to Meckel's Diverticulum SELWYN
Taylor, Lancet Lond., 1947 2 786

The discovery of a Meckel's diverticulum during a laparotomy comes as a surprise to most surgeons for it is an uncommon congenital abnormality. Harkins (1933) who collected all the cases recorded when complete examination of the gastrointestinal tract was made postmortem found that in 25,149 autopsies this abnormality was present on 327 occasions—an incidence of 1.3 per cent. Among 69,000 admissions to the Truesdale Hospital Atwood (1946) has reported 37 patients with symptoms due to a Meckel's diverticulum. In the records of King's College Hospital there are numerous references to the finding of Meckel's diverticulum during abdominal operations, but only 11 times in the 18 years from 1928 to 1945 was this the actual cause of the symptoms which necessitated surgical intervention.

Thirteen cases are briefly reviewed with the addition of 1 case of different causation, as a result of which it is tentatively suggested that Meckel's diverticulum may be involved in the pathogenesis of chronic as well as acute abdominal pain.

Developmentally the vitelline duct connects the yolk sac and the midgut of the embryo at an early stage.

The intestinal portion of the duct persists most commonly and was the one first described by Meckel (1809, 1812).

The complications arising in connection with Meckel's diverticulum are briefly as follows: intestinal obstruction due to a band or to volvulus; perforation into the peritoneum; ulceration of heterotopic gastric mucosa (producing hemorrhage as indicated by melena and perforation); foreign body neoplasm; aberrant pancreatic tissue; and strangulation in the hernial sac (Littre's hernia).

An analysis of the last 11 cases of acute abdomen admitted to the hospital in which a Meckel's diverticulum was the causal factor shows examples of practically every known complication and confirms the opinion of previous writers on the subject that the correct diagnosis is rarely made before operation.

The most common situation for this development is 18 in. from the ileocecal valve but it has often been discovered from 12 to 36 inches from the end of the ileum; therefore unless the whole terminal 3 feet of ileum are inspected it may be overlooked.

Meckel's diverticulum should be looked for more often and more carefully especially in laparotomies in which the other abdominal organs do not appear sufficiently abnormal to explain the signs and symptoms.

HARRY W. FINK, M.D.

Carcinoma of the Large Intestine. ARTHUR W.
Allen, Surg. Clin. N. America 1947 57 1018.

Five case reports are presented to illustrate the usual procedures which were found satisfactory in the management of malignant lesions of the colon. With experience the method of choice has become resection with primary anastomosis. This growing tendency toward primary suture of the bowel has evolved through improvements in preparation of the patient, better surgical technique and chemotherapeutic aids. The author believes that the morbidity could be reduced by primary suture and the mortality rates could be kept as low as those reported by the advocates of the Mikulicz's principle.

An aseptic anastomosis is now not considered important because with better bowel preparation a satisfactory primary anastomosis can be obtained by the so-called open technique. Also complementary proximal decompression is used less frequently. Preliminary cecostomy is now done only in the presence of acute and complete obstruction of the left colon, and complementary cecostomy is rarely done. The Miller Abbott tube is used as an added precaution in some cases.

Preliminary transverse colostomy is used only in large obstructing inflammatory lesions of the sigmoid. This procedure is mandatory in diverticulitis with inflammatory extension and by this means one can count on the resolution of the acute process even in the presence of a frank abscess. Since carcinoma and diverticulitis may occur in the same region one

must consider an earlier resection in some cases. If bleeding and mucous discharge continue from the defunctioned segment, the diagnosis of cancer is established and the obstructive inflammatory features may be secondary to the malignant process. If cancer is obvious or strongly suspected the resection should be undertaken not later than the fourth week after transverse colostomy. If it seems reasonably certain that diverticulitis is the sole causative factor a better procedure can be accomplished after 3 to 6 months of decompression.

Following this discussion of the subject, case reports on (1) carcinoma of the cecum treated by end-to-end anastomosis, (2) carcinoma of the transverse colon treated by end-to-end anastomosis plus bilateral prophylactic superficial femoral vein interruption, (3) carcinoma of the descending colon treated by end-to-end anastomosis, (4) carcinoma of the rectosigmoid just below the pelvic floor also treated by end-to-end anastomosis, and (5) carcinoma of the sigmoid with endometriosis treated by (a) exploratory laparotomy and complete transverse colostomy and (b) resection of the sigmoid and panhysterectomy en bloc, followed by primary anastomosis of the descending colon to the rectosigmoid demonstrate the surgical procedures utilized.

Adjuvants to Surgical Therapy in Large Bowel Malignancy. L. S. RAYBURN and HAROLD A. ZIMMER. *Ann. Surg.* 947: 36-43, 1953.

The authors suggest the following adjuvants to surgical therapy in malignancy of the large bowel:

1. Correction of anemia and hypoproteinemias by vigorous and repeated blood transfusion.

2. Large doses of vitamins given preoperatively.
3. Long tube decompression in all cases.
4. Chemotherapy (sulfonamides given orally) especially sulfasuxidine and sulfathiazidine. Streptomycin has been used lately.

Minor fecal contamination of the peritoneum at operation did not prove serious, and peritonitis has not been the cause of a single death in the year 1946 during which time 53 colon resections were done, 40 in one stage. Eighteen of the latter were performed by the open method. Prior to the adoption of the complete program as described, the total resectability for cancer of the colon was 64.5 per cent. During the year 1946 the total resectability was 78.6 per cent. The mean operative mortality from 1923 to 1938 was 18.4 per cent; since 1938 a definite portion of the program was used and the mean mortality was reduced to 3.6 per cent. In only 3 years prior to 1938 was the mortality ever as low as it has been in any year since 1938.

Resection with end-to-end anastomosis is supplanting the Mikulicz types of resection in the authors' clinic. On-stage procedures have entirely supplanted multistage operations except in the presence of perforation or obstruction.

Nothing replaces the gentle handling of the bowel, the greatest care in the conservation of the blood

supply, the prevention of major soiling, and the careful approximation of the bowel edges. However, in spite of this a number of patients will still lose their lives because of peritonitis from one cause or another. The adjuvants suggested have permitted a large number of one-stage in place of multistage operations, which reduces the risk of secondary anasthetization and they have led to more rapid recovery and a shorter period of disability and hospitalization in a larger number of patients. They have led to a substantial reduction in the mortality following operation on the colon and have played an important part in the very marked reduction in the incidence of fatal peritonitis following resection of the large bowel.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Thrombosis of the Hepatic Veins: The Budd-Chiari Syndrome. R. B. THOMPSON. *Arch. Int. M.* 947: 80-803.

The author reports 3 cases of thrombosis of the hepatic veins and reviews 95 of more than 100 in the literature to emphasize that this syndrome is not always due to one disease process as is so commonly implied and to attempt to give a clearer conception of the various other processes which may cause it.

In the majority of the reported cases there was gross obstruction of the hepatic veins, which led to engorgement and necrosis of the liver and to portal obstruction.

It was proposed that the name Chiari or Budd-Chiari syndrome should be retained for cases in which there is gross blockage of the hepatic veins and that cases with more limited lesions not giving the full picture, should be referred to simply as cases of thrombosis of the hepatic veins. While this article is primarily concerned with the Chiari syndrome, remarks concerning the etiology and pathology of the latter type of cases are included also. Two previously accepted cases have been excluded.

The lesions found in the liver depend on the duration of the thrombosis. In the acute stage there is severe venous engorgement resulting in central lobular necrosis of the hepatic cells. Later cirrhotic changes develop and nodular regenerative hyperplasia is common.

The clinical features include abdominal pain which is usually the initial symptom. It precedes hepatic enlargement and ascites and is one of the most constant features.

The presence of venous collaterals is also one of the most important signs. Only a few reports mention a caput medusae.

The absence of gross jaundice and the presence of the slight, latent, or clinical form are the most important features.

The first correct diagnosis was made by Willcocks in 1866. Since then the syndrome has been diagnosed during life in 10 cases, including the 3 cases presented here. The great majority of cases present such

a typical picture that there are not many other disease pictures which resemble it.

The duration is variable. In the majority of cases the disease is of short duration in some lasting only a few days while in a smaller group the disease may last from 10 to 28 years.

The treatment of this disease unfortunately, does not offer much scope for discussion. It must be on the same lines as the treatment for portal cirrhosis. One point of great importance is that although this is an extremely fatal disease patients may live for many years before succumbing perhaps to a fresh thrombosis.

HARRY W. FINK, M.D.

Total Volvulus of the Gall Bladder (Volublo total de la vesícula biliar) GUSTAVO E. E. ANSCHUTZ *Bol Acad argen cir.*, 1947 31 806

In the world literature there were only 91 cases of total volvulus of the gall bladder reported up to the year of 1945.

The author reports this condition in a female 71 years of age. The symptoms were those of an abdominal crisis, namely, pain in the right hypochondrium, continuous vomiting, tenderness in the right hypochondrium and right iliac fossa, and no audible peristalsis.

X-ray examinations revealed a large tumor mass occupying the right flank and compressing the hepatic flexure of the colon. There also was a ptosis of the transverse colon.

On opening the abdomen the gall bladder was found to be the size of a large pear, free and erect. The cystic duct was twisted and it was impossible to visualize the cystic artery. The gall bladder was edematous and friable. It contained a great number of calculi and was filled with a black sanguino purulent, bile stained fluid.

The author stresses the value of x-ray examination in the diagnosis of this condition and believes that a large cystic duct with rudimentary mesocystic tissue in a thin patient with abdominal ptosis favors the development of volvulus.

ARTHUR I. CIFOLLA, M.D.

Considerations on the Pathogenesis of Calcified Gall Bladder (Considerazioni sulla patogenesi della colecisti di porcellana) PAOLO BIOCCA *Pediatrica sez chir.* 1947 54 173

The literature upon what is termed "calcified cholecystitis," porcelain cholecystitis, enameled cholecystitis, or "petrified cholecystitis" is reviewed. About 30 cases have been reported, 14 of which occurred in Italy. The condition is rare and Kirkland reports only 4 cases observed in 6,000 cholecystectomies at the Mayo Clinic. Of 10 cases reported by Pheasant, 4 were found at autopsy.

The clinical picture is usually that of mild gall bladder disease which usually occurred some time previously and had caused little or no disturbance since. The diagnosis is usually made by x-ray examination which reveals a radiopaque shadow in the upper right quadrant. The cortical area of the shadow

is usually most marked except for a small area near the neck which is considered to be diagnostic of gall bladder calcification rather than calcified echinococcus cyst of the liver or calcifications of the ribs, kidney, mesentery or peritoneum, from which it must be differentiated. The radiologic diagnosis is usually easy.

Two case reports are presented. One of a woman 70 years of age who was operated upon and found to have a walled-off perforated empyema of the gall bladder together with a calcified gall bladder. It was drained and she was discharged after a month with a partial biliary fistula. The patient died 11 months later of an acute pulmonary affection. The second case occurred in a 71 year old male. The gall bladder was palpated during routine examination for inguinal hernia and the condition was confirmed by roentgenography. Surgery was not advised.

The various causes for this condition as presented by different authors are discussed. According to the author of this article the pathogenesis of calcification of the gall bladder is as follows: a chronic stimulus, mechanical or infectious, produces a productive connective tissue reaction accompanied by mesoarteritis and endarteritis which is ultimately responsible for sclerosis of the involved vessels. A lipid infiltration associated with transitory hypercholesterolemia supervenes upon elements with diminished vitality (caused by a persistent local stimulus and deficient nutrition) and accentuates degenerative processes which lead to necrosis. Upon these necrotic areas the lipid infiltration produces a precipitation of calcium salts. LUCIAN J. FRONZOTTI, M.D.

The Method of Dissolution of Common Duct Stones Remaining after Operation B. O. C. PRIBRAM *Surgery* 1947 22 806

It is well known that stones in the common duct may be easily overlooked during an operation, however the frequency of this incident is not generally appreciated. It appears to be a fact that stones are left behind in from 16 to 25 per cent of all patients operated upon for choledocholithiasis even by the most experienced surgeons. Retroduodenal and transduodenal exposure of the papilla are operations which decrease the probability of missing common duct stones. Such operations have the relatively high mortality of 20 per cent and most surgeons are reluctant to use them in poor risk patients.

Two techniques have been developed to improve the result in operations for choledocholithiasis. Minzu's method of cholangiography during the operation and Pribram's method for postoperative dissolution of gallstones remaining in the common duct under cholangiographic control.

Cholangiography during the operation enables one to discover stones in the common duct which otherwise might be missed, but even with this method it is difficult to be certain that all stones have been removed. In a case in which multiple stones have been removed even though cholangiography has been carried out during the operation the surgeon should

never omit drainage of the common bile duct which provides opportunity for further cholangiographic studies in the post operative period.

The scaffolding of the usual gallstone is made up of cholesterol which is soluble in ether. By dissolving the scaffolding ether disrupts the structure of a stone, causing it to crumble into a mud the particles of which can easily pass through the papilla. The ether method therefore, is effective only against stones containing cholesterol.

It is of considerable practical importance to know that there is a good method of dealing with overlooked duct stones in the postoperative period under cholangiographic control. In the author's 51 cases in which the ether method was used for the post operative dissolution of gallstones remaining in the bile ducts there have been no failures nor has a secondary operation been needed. Failures reported by other surgeons must be due to a difference in technique. The first consideration is that of the solvent which is exclusively ether. The T tube for drainage of the common duct is not suitable with the ether technique because the ether evaporates upward into the liver instead of reaching the stone. For this and other reasons a catheter or simple tube stitched into the common duct is preferred. The surgical therapy for cholelithiasis consists of removal of the gall bladder opening of the common duct, removal of all stones possible insertion of a double barreled catheter downward into the common duct until the tip touches the stones in the ampulla, and closure of the wall of the common duct around the catheter with 5 silk sutures. On the fifth postoperative day the first cholangiogram is made with from 5 to 10 cc of warm lipiodol. When there is evidence of stone the ether treatment is initiated with ether injected drop by drop. The whole procedure may be repeated several times a day and continued for at least a week, after which another cholangiogram is made. With the gradual crumbling of the stone the tube can be passed easily through the open papilla into the duodenum. The time required for the dissolution of stones varies greatly and depends upon many factors. In many instances the patient has been dismissed from the hospital after 14 days with the choledochostomy tube in place and then treated as an outpatient. The time required for the dissolution of calculi varies from 1 to 6 weeks. The great advantage of this method rests in its safety and harmlessness.

SAMUEL J. FOGELSON M.D.

The Anatomy of the Pancreatic Ducts. The Etiology of Acute Pancreatitis. JOHN HOWARD and RALPH JONES. *Am J Med Sc* 947 4-67

The anatomy of the pancreatic duct system and of its relationship to the lower end of the common bile duct has been a subject of much interest since 1901 when Opie first presented his "common channel" theory of the etiology of acute hemorrhagic pancreatitis. This theory found its origin in Opie's now classic study of specimens removed at autopsy in a case of acute hemorrhagic pancreatitis in which a

small biliary calculus was found impacted in the papilla of Vater, converting the duct of Wirsung and the common bile duct into a common channel so that there had been a reflux of bile into the main pancreatic duct. The theory that the pancreatitis had been caused by the reflux of bile into the pancreatic tree was well founded because Claude Bernard had previously shown that the injection of a mixture of bile and olive oil into the pancreatic duct produced the disease in experimental animals. Opie's theory has subsequently been the subject of much study and considerable criticism, but many authors now agree with the opinion of Dragstedt that the common channel theory probably explains 60 to 70 per cent of cases of the disease in man.

It was originally thought that a calculus impacted at the ampulla of Vater was responsible for the formation of a common channel in all cases of pancreatitis, but subsequent studies of specimens at autopsy have shown that a calculus is the obstructing agent in not more than 10 per cent of clinical cases of this disease. On the basis of Archibald's work in animals, it is now believed that segmental spasm of the sphincter of Oddi is the obstructing agent which creates the common channel in the majority of clinical cases of the disease.

There are a number of prerequisites that must be fulfilled before Opie's common channel theory can be accepted. The first of these, as Opie realized is that the anatomic possibility of the formation of a common channel in a reasonable percentage of people must be established. It is obvious that the 2 ducts must unite to form a common ampulla before emptying into the duodenum and that the union must occur at a sufficient distance from the duodenal orifice to allow for obstruction of the orifice without obstruction of either of the ducts.

That a common channel exists in a limited number of persons has been proved in vivo by cholangiography. This study does not necessarily demonstrate all cases in which reflux is possible but it does offer evidence in vivo that reflux is anatomically possible.

The present study consisted of examination of 150 fresh unfixed specimens consisting of pancreas, duodenum, and common bile duct removed intact at autopsy at the Philadelphia General Hospital.

In 81 of 150 cases (54%) a common channel was created by the methods described and reflux of the injection fluid into the duct of Wirsung occurred. In 69 (46%) no reflux was demonstrated.

A patent duct of Santorini connecting the duct of Wirsung with the duodenum was demonstrated in 35 per cent of 150 cases.

In 44 per cent of the 81 cases in which reflux at the ampulla of Vater occurred, a patent duct of Santorini connecting the duct of Wirsung with the duodenum was demonstrated.

The authors conclude that this evidence confirms the finding of Cameron and Noble that the anatomic possibility for the formation of a common channel at the ampulla of Vater exists in at least 50 per cent of persons.

BENJAMIN GOLDMAN M.D.

Carcinoma of the Islets of Langerhans. Review of the Literature. BENJAMIN S. GORDON and RENE G. OLIVETTI *Gastroenterology* 1947 9 409.

In the Introduction of this paper the authors point out that prior to the discovery of insulin in 1922 very little interest existed in the subject of pancreatic islet cell tumors. However since the great discovery of Banting and Best, interest in these neoplasms has been progressively intensified.

Yet the number of islet cell tumors which are indubitably malignant are very few. The authors regard direct invasion of other organs or metastases as their criterion of malignancy. Classification of malignancy on the basis of histologic appearance alone is not acceptable evidence by the authors' standards. They have culled 20 cases from the literature and these are briefly reviewed. In addition they present in detail 2 of their own cases.

The authors conclude that carcinoma of the islets of Langerhans is a rapidly growing tumor which occurs more commonly in males, is more frequent in middle life, may or may not produce hypoglycemia, arises most often in the tail of the pancreas and metastasizes quickly and widely to neighboring and distant structures but most often to the liver and to nearby lymph nodes.

The duration of illness from the first definite symptoms to the time of death is variable. Of the 19 patients in whom the duration of illness was reported the largest number (8) had their first symptoms 6 months prior to death.

A discussion concerning the pathogenesis of islet cell tumors is presented and the authors conclude that the islet cells develop by a process of differentiation from the epithelium lining the smaller pancreatic ducts. Tumors may arise from mature well differentiated islet cells or from undifferentiated ductal epithelium.

MISCELLANEOUS

Neurogenic Abdominal Sarcoma (Sarcoma neurogenico abdominali). J. A. PÉREZ ALBARRÁN, F. PÉREZ MONTES, J. A. ACOSTA MONTEJO and M. S. BALAMBRIN *Rev. med. cir. Habana* 1947 53 320.

The authors present a case of acute abdominal crisis from a hemorrhagic neurosarcoma of the mesosigmoid. The patient was a 61 year old woman who was suffering from acute abdominal pain and fever. Examination revealed a hypogastric tumor on the left side with exquisite abdominal tenderness over the area. Shock appeared imminent and a tentative diagnosis of torsion or rupture of an ovarian cyst was made. Emergency operation revealed a large gray tumor with the appearance and consistency of the cerebrum. The mass was loosely attached to the anterior parietal peritoneum and to the fundus of the uterus, and was firmly embedded in the posterior parietal peritoneum and mesosigmoid from which it obtained its blood supply. Recent hemorrhage was evident and the pouch of Douglas was found to be filled with clotted blood.

The tumor was removed in its entirety. Complete recovery followed a stormy postoperative course and there was no evidence of the disease on roentgen examination 15 months later.

The tumor was the size of a grapefruit, irregularly ovoid, and its cellular components showed frank sarcomatous characteristics associated with glial nerve elements. A review of the literature revealed only 8 other indisputable similar cases. Histogenic studies showed the origin of the tumor to be from the sheath of Schwann.

The article gives a good summary of the history, histogenesis, etiology, frequency, location, pathologic anatomy, clinical study, symptoms, course, prognosis, and treatment of this disease.

STEPHEN A. ZIEGLER, M.D.

never omit drainage of the common bile duct which provides opportunity to further cholangiographic studies in the postoperative period.

The scaffolding of the usual gallstone is made up of cholesterol which is soluble in ether. By dissolving the scaffolding ether disrupts the structure of a stone causing it to crumble into a mud the particles of which can easily pass through the papilla. The ether method therefore is effective only against stones containing cholesterol.

The time required for the dissolution of stones varies greatly and depends upon many factors. In many instances the patient has been dismissed from the hospital after 14 days with the choledochostomy tube in place and then treated as an out patient. The time required for the dissolution of calculi varies from 2 to 6 weeks. The great advantage of this method rests in its safety and harmlessness.

SAMUEL J. FODERSON, M.D.

The Anatomy of the Pancreatic Ducts. The Etiology of Acute Pancreatitis. JOHN HOWARD and RALPH JONES. *Am J S Sc* 947 14.67

The anatomy of the pancreatic duct system and of its relationship to the lower end of the common bile duct has been a subject of much interest since 1901 when Opie first presented his "common channel" theory of the etiology of acute hemorrhagic pancreatitis. This theory found its origin in Opie's now classic study of specimens removed at autopsy in a case of acute hemorrhagic pancreatitis in which a

small biliary calculus was found impacted in the papilla of Vater, converting the duct of Wirsung and the common bile duct into a common channel, so that there had been a reflux of bile into the main pancreatic duct. The theory that the pancreatitis had been caused by the reflux of bile into the pancreatic tree was well founded because Claude Bernard had previously shown that the injection of a mixture of bile and olive oil into the pancreatic duct produced the disease in experimental animals. Opie's theory has subsequently been the subject of much study and considerable criticism, but many authors now agree with the opinion of Dragstedt that the common channel theory probably explains 60 to 70 per cent of cases of the disease in man.

It was originally thought that a calculus impacted at the ampulla of Vater was responsible for the formation of a common channel in all cases of pancreatitis, but subsequent studies of specimens at autopsy have shown that a calculus is the obstructing agent in not more than 10 per cent of clinical cases of this disease. On the basis of Archibald's work in animals it is now believed that segmental spasm of the sphincter of Oddi is the obstructing agent which creates the common channel in the majority of clinical cases of the disease.

There are 5 important prerequisites that must be fulfilled before Opie's common channel theory can be accepted. The first of these, as Opie realized, is that the anatomic possibility of the formation of a common channel in a reasonable percentage of people must be established. It is obvious that the ducts must unite to form a common ampulla before emptying into the duodenum and that the union must occur at a sufficient distance from the duodenal orifice to allow for obstruction of the orifice without obstruction of either of the ducts.

That a common channel exists in a limited number of persons has been proved in vivo by cholangiography. This study does not necessarily demonstrate all cases in which reflux is possible but it does offer evidence in vivo that reflux is anatomically possible.

The present study consisted of examination of 150 fresh, unfixed specimens consisting of pancreas, duodenum, and common bile duct removed intact at autopsy at the Philadelphia General Hospital.

In 81 of 150 cases (54%) a common channel was created by the methods described and reflux of the injection fluid into the duct of Wirsung occurred. In 69 (46%) no reflux was demonstrated.

A patent duct of Santorini connecting the duct of Wirsung with the duodenum was demonstrated in 36 per cent of 50 cases.

In 44 per cent of the 81 cases in which reflux at the ampulla of Vater occurred, a patent duct of Santorini connecting the duct of Wirsung with the duodenum was demonstrated.

The authors conclude that this evidence confirms the finding of Cameron and Noble that the anatomic possibility for the formation of a common channel at the ampulla of Vater exists in at least 50 per cent of persons.

BENJAMIN GOLDSMAN, M.D.

A first series of experiments allowed the authors to answer these criticisms. Massive doses of estradiol benzoate were administered to young guinea pigs, intact or castrated at weekly intervals for several months. From these experiments three important conclusions were derived:

1. The adenocystic endometrial hyperplasia is not only inconstant but purely coincidental. The formation of cysts in the hyperplastic myometrium results from obliteration of the glandular ducts by a fibrous process.

2. The experimental lesions of the myometrium were polymorphic. Between these lesions and those of the spontaneous fibromyoma there is a definite difference, but the similarities between the two by far exceeded the dissimilarities.

3. The vascular factors play a fundamental role in the genesis and growth of a large number of experimental tumors. The proliferation of the vascular endothelium is the origin of numerous genital and extragenital tumors which are at first small angiomatous formations. An extensive fibrosis transforms the angiomatous nodules into an homogenous fibrous mass. This fibrous necrosis chokes the hyperplastic reactions of the connective tissues and epithelium.

Believing that a relation might exist between the degree of the fibrous process and the size of the doses of injected hormones a second series of experiments was carried out by the authors, using much smaller doses of estradiol benzoate. The results were in conformity with the authors' expectations: namely if the fibrous reaction is still present the hyperplastic phenomena are more evident and varied.

The nature of the cells which participate in the hyperplasia of the uterine muscles during gestation and various pathological experimental conditions has always been a matter of controversy. The authors quoted Keesler who stated that the multiplication of smooth muscle fibers results from a muscular differentiation (metaplasia) of the connective elements the fibroblasts. These fibroblasts would exist in the nonpregnant uterine muscle but they would be hidden between the smooth muscle fibers.

The authors claim that in the guinea pig there are no cellular elements similar to the fibroblasts described by Keesler. In the hyperfolliculinized female animal, the increase in number of the smooth muscle fibers is not the result of differentiation of pre-existing elements: it is conditioned by the proliferation of the vascular endothelium and the connective tissue cells surrounding them. These later on differentiate into smooth muscle fibers which by peripheral apposition form a regular thickening of the muscular fasciculi.

By studying the microscopic slides of the myometrium the authors have noticed mitoses to be most numerous in the external layers of the circular tunica. At this level there are large congested venous capillaries. Undoubtedly there is a relationship between the passive congestion and the degree of hyperplasia. It is probable that the passive congestion of certain vascular areas is in close relationship with

special vascular elements present in the uterine wall the action of which is perhaps initiated through sympathetic or parasympathetic nervous elements in response to hormonal excitation.

In the authors' opinion the excess of folliculin is the causative factor in the development of fibromyoma of the uterus. Furthermore the vascular reaction plays a fundamental role in the mechanics of its development.

GERARD GAGNON, M.D.

Data on the Treatment of the Fibromyomas of the Uterus Observed in 1945 and 1946, at the Obstetric and Gynecologic Clinic of Strasbourg (Remarques sur le traitement des cas de fibromyomes de l'utérus observés dans 1945 et 1946 à la Clinique d'Obstétrique et de Gynécologie de Strasbourg) R. KELLER and PH. PAQUET. *Rev fr gyn obst* 1947 42: 193

Two hundred and fifty-one patients with fibromyoma of the uterus were seen by the authors from May 1945 to July, 1946. A review of this series showed that 61 patients were in the fourth decade, 146 in the fifth decade, 42 in the sixth and 2 in the seventh. In 22 patients the fibromyoma was silent and was an incidental finding. In 16 instances the fibromyoma was a complicating factor of pregnancy, all but 2 of the 16 patients carried their pregnancy to full term. All of the patients experienced one or more of the following symptoms: (1) pain, (2) vaginal bleeding, (3) pressure, (4) dysuria, (5) weight loss, (6) increase in size of the abdomen, and (7) dyspareunia.

Conservative or medical treatment was used in 100 patients (40%) with 6 failures. This consisted of the administration of from 150 to 400 mgm. of acetosterandryl a month. It was given to young women with small painless fibromyomas and to old women whose general condition was poor. The size of the tumor alone was not an indication for operation.

One hundred and forty-seven patients (57%) were operated upon. The authors recommend operation when dealing with painful myomas, even if small myomas producing pressure symptoms; fast growing tumors; myomas associated with severe hemorrhage; intraligamentary and cervical myomas; myomas refractory to roentgen therapy, and obscure cases in which a definite diagnosis cannot be made clinically.

The operation of choice in the authors' opinion is myomectomy since the possibility of future pregnancy is preserved. Myomectomy is advocated (1) for women less than 35 years of age, (2) for sterile women, (3) when fibromyoma is associated with pregnancy, (4) when the growth however large is on the fundus, and (5) when fibromyomas are associated with prolapse. Myomectomy is carried out during pregnancy if the tumor is fast growing or painful, or if the fibromyoma is associated with retroversion of the uterus. Myomectomy is seldom performed during labor because of the high incidence of infection. During the postpartum period hysterectomy is preferred if infection already exists.

GYNECOLOGY

UTERUS

A Personal Method for the Surgical Cure of Uterine Retroflexion (Procedo personal per la cura chirurgica della retroflessione uterina) GIULIO RICCIMA. *Ann. Ital. chir.* 947 34 392.

A new method for the operative correction of retroflexion of the uterus is described by the author. One can foretell, by the results obtained from the one case reported that this type of repair does not expose the uterus to the grave danger of rupture during the contractions of labor. Even though there are uterine modifications the technique is simple.

A suprapubic transverse incision is made through the skin and subcutaneous tissue. After the fascia is incised by means of a vertical incision the rectus muscles are retracted laterally and the peritoneum is opened. The uterus is exteriorized and the retroflexion is reduced manually. Next a semicircular incision is made on the superior-anterior surface of the fundus down to the first and second layers of the myometrium. The curved portion of the incision is superior while the open ends are inferior. The superior lip is imbricated over the inferior lip and fixed in place with sutures, to correct the retroflexion. The length and height of the limb should be in proportion to the volume of the organ and to the degree of flexion. ARTHUR F. CIPOLLA, M.D.

Radical and Conservative Treatment of Uterine Ruptures (Sobre tratamiento radical y conservador de las roturas uterinas) CARMEN LOZANOSARAO. *ANAYA. Arch. Soc. cir. hosp. Santiago*, 947 7 470.

Within a period of 6 years and 5 months beginning with 1931 23 patients with uterine rupture during labor were operated upon at the Ramón Barros Luco Hospital. 13 were submitted to hysterectomy and 9 to simple laparotomy with repair of the lesions.

The first group included 5 complete ruptures and 8 subserous ruptures. The rupture involved the lower segment in 6 cases, the lower segment and the body in 6 and the body only in 1 case. It was due to an obstetrical maneuver (usually internal version) in 8 cases, to faulty assistance in the home in 3 and to spontaneous evolution at the hospital in 2 cases. Factors favoring the rupture were the presence of a cesarean section scar in 2 cases, low placental insertion in 3 and myomatous degeneration of the uterus in 1 case. The operation was performed immediately after the accident in 8 cases and a number of hours after the accident in the remaining 5 cases. There were 5 deaths, a mortality rate of 38.4 per cent. The cause of death was acute anemia and shock in 3 patients, peritonitis in 1 patient, and pyemia with multiple suppurative foci deep to sulfonamide and penicillin therapy in 1.

The second group included 3 complete ruptures and 7 subserous ruptures. The lesion was confined

to the lower segment in 8 cases and extended to the uterine body in 1 case. It was due to previous obstetrical maneuvers in 5 patients, to faulty assistance in the home in 3 and to spontaneous evolution at the hospital in 1 patient. The rupture occurred in a cesarean section scar in 2 cases. Repair consisted of simple suture of the lesion or suture associated with isolation of the involved area of the peritoneal cavity. drainage also was used, and all patients were given sulfonamides or penicillin locally and intravenously. There were 3 deaths, a mortality of 33.3 per cent. The cause of death was acute anemia in 2 patients and septicopyemia in 1 patient. Of the 3 patients in whom simple suture was used with drainage of the peritoneal cavity in 1 patient and local sulfonamide in 2 patients, 2 died. Of the remaining 6 patients in whom suture was combined with isolation of the involved area, only 1 died as a result of the development of infectious dehiscence of the uterine suture.

The author feels justified in concluding that, apart from the clinical conditions which must guide the conduct of the surgeon the surgical technique and the anti-infectious measures actually used in cesarean section are of great importance in the conservative treatment of uterine ruptures.

The mortality rates for the two groups of cases should not lead to the belief that the advantage lies in conservative treatment. The apparently more favorable results in these cases were due to the different clinical conditions under which treatment was instituted. The first group included 5 complete ruptures and 7 lesions which involved the uterine body while the second group included only 2 complete ruptures, and 1 spreading to the uterine body. The conservative treatment cannot be applied in all cases. The problem consists in judging whether the condition would respond to conservative treatment, while keeping in mind that radical operation offers the best guarantee for the survival of the patient.

RODMAN KEMEL, M.D.

New Experimental Contribution to the Study of the Pathogenesis of Fibromyoma of the Uterus. (Nou-elle contribution expérimentale à l'étude de la pathogénie du fibrome utérin) J. DUCONOT, P. GUILLERMIN, and C. BRUNES. *Gyn. Obst., Par.* 947 46. 432.

In a previous paper the authors discussed the various anatomoclinical and experimental factors favoring the theory of hyperfolliculism in the production of fibromyomas of the uterus. The two main criticisms held against such a theory are the inconspicuity of endometrial adenocarcinoma hyperplasia in the bearers of fibromyoma, which is considered the best test for determining the hyperfolliculism syndrome and the existence of essential differences between the spontaneous and the experimental fibromyoma.

for connective tissue but developed in a fine argentine network with which they are intimately connected for the time being these cells are called epithelioid cells to facilitate description.

Because of their characteristics the fibroblastic elements can easily be classified from the histogenetic point of view as thecal cells which are only slightly differentiated and show no tendency toward luteinization but classification of the epithelioid cells which constitute the major part of the tumor is more difficult. Their morphologic characteristics do not agree with those accepted for the cells of the theca and the granulosa, whether these cells are only slightly or greatly differentiated. The absence or at least the scarcity of intercellular fibrillary network militates against their thecal origin, as does also the poor amount of lipid without birefringence observed in them. The absence or scarcity of intercellular fibrils and of fatty substances together with the presence of peculiar arrangements in rosette form of some of the elements would suggest that these cells have originated from the granulosa but have no tendency to luteinization and even maturation. They would consequently be immature elements of the granulosa. In addition there would be some cells of thecal origin which would be a normal finding.

In the present case there were not only a few thecal elements but numerous tracts of them with prevalently peripheral arrangement as opposed to the more central arrangement of the cells of granulosa origin. This tumor would thus be a mixed one composed of immature cells of the theca and granulosa.

On the basis of these observations and considerations, the diagnosis of granulosa cell tumor was made. No macroscopic or microscopic suggestion of malignancy was found and the clinical condition of the patient at the time of the author's study allows the hope that cure will be permanent.

RICHARD KEMEL, M D

EXTERNAL GENITALIA

A Roentgenological Study and the Surgical Treatment of Congenital Transverse Occlusion of the Vagina (Etude radiologique et traitement chirurgical des cloisons transversales du vagin d'origine congénitale) A. GRANJON. *Gyn obst Par.*, 1947 46 303.

Complete occlusion of the vagina without any opening is extremely rare. Different methods have been used for repair of this malformation. The old method of excising the occluding membrane from below has been abandoned by many men because of the danger of secondary infection. Cases of fatal peritonitis after operation have been reported in the older literature. On the other hand the extravaginal way of repair by laparotomy is unnecessary in most cases and is a bigger intervention than is justified by the condition. Furthermore, the modern methods of local and systemic chemotherapy assure effective protection against infection from the vagina.

Before deciding on the method of procedure, the author performs a celloscopy in every case. If the tubes are distended laparotomy is indicated to treat the hematosalpinx by incision or resection. If the tubes appear normal, the diaphragm is opened by simple incision and the hematosalpinx is evacuated. The condition of the uterus and adnexa is investigated and if the cervix is open the uterus is evacuated. The plastic repair of the occluding membrane is postponed to a second operation.

In the more common cases of incomplete occlusion a catheter is introduced through the opening in the membrane and lipiodol is injected through the orifice in the membrane for colpohysterosalpingography. In these cases celloscopy is unnecessary as the permeability of the tubes can be verified by the salpingography. As to the surgical technique, the author is opposed to simple excision of the membrane

Fig. 1 (Granjon). Frontal section of the vagina. Schematic drawing of the incisions of the 2 aspects of the diaphragm. Inferior aspect: V-shaped incision. Superior aspect: anteroposterior incision.

Fig. 2. Inferior aspect of the diaphragm after incision in shape of V. The point of the V is at the orifice of the diaphragm. The flap of the dissected inferior mucosa is temporarily reflected downward.

Fig. 3. Superior aspect of the diaphragm. After anteroposterior incision the two edges of the superior mucosa are separated.

Myomectomy is contraindicated for: (1) patients over 45 years of age (2) tremendously large tumors (3) the presence of inflammatory lesions of the adnexa (4) the presence of carcinoma of the fundus or cervix, (5) fibromyomas associated with hemorrhage and (6) fibroma of the cervix. Cervical erosions are not a contraindication to myomectomy.

Supracervical hysterectomy was carried out 94 times with preservation of one or both adnexa and 18 times with removal of the adnexa. Cancer arising from the cervical stump is uncommon according to the authors who reported 3 cases among 21. Total abdominal hysterectomy was performed 5 times. Vaginal hysterectomy was done only when the growth was small and the uterus freely movable. Six patients were treated with radium and 4 were treated with roentgen rays. The authors believe roentgen therapy is indicated when dealing with large tumors after failure of medical treatment when the general condition of the patient does not warrant surgery. The authors reported 2 operative deaths (2.4%). The reported morbidity was very low.

GERARD GAGNON, M.D.

Limits of the Differential Histopathologic Diagnosis between Adenocarcinoma of the Cervix and Adenocarcinoma of the Uterine Body (Limiti della diagnosi istopatologica differenziale fra adenocarcinoma della cervice adenocarcinoma del corpo dell' utero) EUGENIO LUCCHI. *Riv. Ital. g.* 946, 29, 494.

A comparative study of the histopathology of 14 adenocarcinomas of the cervical canal and 55 adenocarcinomas of the uterine body revealed no characteristic elements which could be considered conclusive for the differential diagnosis of the two tumors, but if the elements prevailing in each of the two forms are taken into account and evaluated together instead of separately it will occasionally be possible to arrive at a highly probable diagnosis by observing the following characteristics:

1. Although the secretion of mucus does not belong exclusively to cervical carcinoma, it is more frequent and abundant in this tumor if a secretion is found also in adenocarcinoma of the uterine body it is not always one of mucus and it is therefore an excellent rule to apply the specific staining method for mucus so as to confirm or exclude the presence of the substance.

2. In cervical carcinoma there is a certain uniformity and an equality in the degree of maturity.

If a given portion of the tumor even if examined in various zones while in adenocarcinoma of the uterine body there is a certain polymorphism and a diversity in the degree of maturity of the epitheliomatous proliferation.

3. In cervical carcinoma an inverting type of development seems to prevail, while in adenocarcinoma of the uterine body the preceding development is especially associated with the everted type and more particularly if the tumor has a tendency toward a papilliferous picture.

4. In cervical carcinoma it is easier to find a small cell infiltration and a histoid reaction.

5. Necrotic phenomena which are not rare in tumors of the uterine body would seem to be more frequent in cervical carcinoma, together with some degree of hyaline degeneration of the stroma.

The histopathologic diagnosis is conclusive only when the examined material presents tracts of healthy tissue in one of the localizations in such continuity with the epitheliomatous proliferation as to leave no doubt about the origin of the neoplasm from the specific epithelial matrix of the site. In other cases the histologic findings play only a complementary and confirmatory role, and the differential topographic diagnosis between tumor of the uterine body and that of the cervical canal must depend especially on the evaluation of the clinical data provided by the gynecologic examination the symptomatology and the information obtained from curettage first of the cervical canal and then of the uterine cavity performed separately in two stages.

RICHARD KIMMEL, M.D.

ADNEAL AND PERIUTERINE CONDITIONS

Anatomoclinical Contribution to the Knowledge of Granulosa Cell Tumors (Contributo anatomo-clinico alla conoscenza dei tumori della granulosa) MASSIMO MACCIOTTA. *Riv. Ital. g.*, 1946, 29, 471.

Histologically granulosa cell tumors present a marked structural polymorphism as some have a distinctly epithelial aspect and others a frankly connective tissue aspect, while still others show a combination of the two giving rise to various pictures which are difficult to interpret and can only be individualized by repeated histologic and histochemical examinations associated with a study of the estrogenic substances. This polymorphism would be better explained by the concept that the elements of the granulosa are not of epithelial but of mesenchymal origin. The structural variability would thus appear more understandable especially if it is kept in mind that the cells of the granulosa may give rise to neoplastic forms at any time of their development and in various phases of their differentiation.

Macciotta has made a histologic study of a solid tumor of the left ovary removed from a woman 46 years of age who 3 years previously had had amenorrhea for 13 months followed by menstruations of menorrhagic type which appeared every 15 to 20 days and later assumed a serious menorrhagic character. Although numerous preparations from various parts of the tumor were examined it was impossible to demonstrate the presence of any follicles of de Graaf or of normal ovarian tissue, the entire tumoral mass seemed to consist of neoplastic elements only. These were of two types: (1) more or less abundant fusiform cells of connective tissue aspect with some indications of hyaline degeneration, and (2) massive groups of cells of various sizes, more or less well stained and nearly always with blurred contours, staining like epithelial elements with the methods

year. However, in only a few instances had the condition become worse than before the operation.

This gives a permanent cure rate of only 55.5 per cent, but this figure does not tell the true story since results have been improving from year to year as the operator has gained in experience and as he has allotted more study to the subject of the relaxation of the pubocervical ligament in particular and of the anatomy of the internal and external genitalia in general. Six women were operated upon in 1943 with 2 permanent cures, 8 in 1944 with 3 cures, 14 in 1945 with 7 cures, and 19 in 1946 with 13 ultimate cures. Results were better on the whole in younger women.

No rigid scheme of operative procedure was observed; the operative procedure to be followed was planned for each individual condition present. In the younger women with a simple stress incontinence, accompanied perhaps by cystocele, an anterior colporrhaphy was frequently all that was done. In the cases in which there was no evidence of downward displacement of the vesical neck other than mild displacement of the carinae urethralis when the patient contracted the abdominal muscles, plication of the urethral sphincter in the midline by Stoeckel's method or Kelly's mattress suture was resorted to. In these cases the author's modification of this operation was usually added. This consisted in a second line of sutures over the first but with plication of the relaxed tissues of the pubocervical fascia at right angles to the deeper suture line. The old Pavlik (Pawlik) method of urethral advancement as modified by Berkow Barger may be resorted to in the conditions which seem to require a lengthening and narrowing of the urethral lumen in addition to supportive procedures. As a rule the operation of uterine interposition was reserved for the patients in whom the incontinence had recurred after the previous operation.

The rather mediocre results of operation despite the evident improvement in later years, have caused the author to focus his attention on prophylaxis. In addition to care to forestall injury to the urethra, base of the bladder and pubocervical fascia during child birth, attempts are being made to train the bladder to empty itself during the puerperium and exercises (Cyriax method) have been instituted to strengthen the muscles of the perineum and abdominal wall.

JOHN W. BRENNAN, M.D.

Diverticula of Female Urethra (Divertículos de la uretra femenina). R. DE SURRA CANARD and J. IZARU. *Rev. argen. urol.*, 1946, 15, 481.

The authors concluded from their endoscopic studies that the juxtacervical segment, or the neck of the bladder in the female, corresponds to the prostatic urethra of man and the lower segment of the female urethra corresponds to the vestibular region of the male urethra.

Observations of 14 cases led the authors to the conclusion that there are two types of diverticulitis, acute and chronic. Purulent and catarrhal types of acute processes may be distinguished.

Fig. 1 (Canard and Izaru). The diverticulum separates the labia of the vulva.

Diverticula may produce a variety of symptoms according to their size, location and evolution. The condition may be easily confused with inflammatory lesions of other organs.

Palpation of a tumefaction in the anterior vaginal wall, congestion of the ducts of Skene's glands, results of endoscopic examination and urethrography help to establish the diagnosis.

Acute catarrhal diverticulitis requires the local application of drugs and massage. Small and medium size diverticula may be treated with the electrocautery while larger ones require extirpation.

JOSEPH K. NARAT, M.D.

Urethroceles. D. K. ROSE. *J. Urol. Balt.* 1947, 58, 549.

By the use of a graphic method the author wishes to offer ideas for analyzing and diagnosing the various types of urethrocele which may be seen in the daily practice of urology. An anatomically prepared female pelvis was presented which had been cut sagittally and accurately in the midline. It showed fibrous urethral attachments from the symphysis pubis to the urethral meatus, the posterior urethra, and to the anterior bladder wall. The latter two attachments spanned the internal bladder orifice. In addition the triangular ligaments supported the mid urethra as well as delineated its membranous portion. Anterior, posterior, or complete urethroceles occur when any or all of these supporting attachments are or become insufficient.

Function of the bladder is altered whenever the viscus or its outlet becomes displaced, either because the pelvic floor support fails, or the urethral attachments are injured in the latter case with or without strong pelvic floor support. The position in which the bladder is maintained plays an important part because of the transmitted pelvic muscle support and fibrous and urethral attachments.

Fig. 4 (Granjon) The inferior flap is reflected upward between the two edges of the incised mucosa. Point A is brought up to A, point B is brought up to B.
Fig. 5. There is an excess of the superior mucosa at the two lateral angles.
Fig. 6. The excess of the mucosa of the external border is utilized for plicating, which increases its width.

because it often results in strictures and mutilating scars. The mucosa covering the occluding membrane from above and below is really a part of the vaginal mucosa. Therefore, as much as possible of this valuable material should be saved. The author reports 6 of his own cases in detail and describes his technique of plastic repair. **WERNER M. SCHAEFER, M.D.**

Dysmenorrhea and Ovulation: Correlation of the Effect of Estrogen Therapy on Pain, the Endometrium, and the Basal Body Temperature. LOREN W. HAYS, JOSEPH W. GOLDBERGER, and E. C. HANSEN. *Am. J. Obs. Gyn.* 1947 54: 820.

One of the most striking characteristics of functional dysmenorrhea is its invariable correlation with a pregestational endometriom or an ovulatory type of basal temperature curve. On this basis it has been concluded that ovulation is a prerequisite for dysmenorrhea, and treatment aimed at the suppression of ovulation has been undertaken. The authors have attempted to correlate the response to therapy with various dosage levels of estrogen.

The effects of treatment were studied during 53 cycles of 50 patients. In the evaluation of data, treatment was considered successful only when there was complete relief of pain. In most instances in which there were failures there was partial relief of pain, but the large personal factor which enters into the interpretation of "partial relief" renders these results of questionable value.

In the untreated cycles, 46 biopsies showed pregestational endometriums, all of which were associated with dysmenorrhea. In those women with dysmenorrhea in whom an estrogenic endometrium was encountered no pain was present during that particular cycle. According to basal temperature records all patients showing an ovulatory rise complained of pain.

Progressively larger percentages of patients became pain-free as dosage levels of premarin (estrone

sulfate) or diethylstilbestrol were used, 72.7 per cent were totally pain-free when treated with from 40 to 60 mgm. of diethylstilbestrol.

In order to establish the optimal dosage for the individual patient, the authors conclude that it is advisable to follow treatment with endometrial biopsies or determinations of the basal temperatures.

No gross menstrual disturbances followed the described schedule of estrogen administration, although the dosage given to some patients was relatively large.

The presence either of progesterone or of its physiologic effects is a prerequisite for dysmenorrhea. Although it is initiated by progesterone other details of the pathogenesis of dysmenorrhea are unknown. **JOHN R. WOLFF, M.D.**

The Surgical Treatment of Stress Incontinence in the Female. A Report of 67 Cases. (Příspěvek k otázce chirurgické léčby relativní inkontinence moče u žen. Zpráva o 67 operovaných případech.) JAROMÍR PADOUŠ. *Česk. gyna.* 1947 31: 343.

Relative urinary incontinence or stress incontinence as it is commonly designated in the Anglo-American literature, predominates in women who have borne one or more children. It does not appear immediately but later in life when senile relaxation of the tissues occurs. A certain number of cases of stress incontinence occur however in women who have never borne children.

In the 3½ years, that is 1943, 1944, 1945 and a part of 1946 61 women were operated upon for incontinence. At the end of 1946 a questionnaire was sent out to inquire if the results of the operation had been permanent. There were 47 replies and it is on these 47 cases that this report is based.

Of those who replied, 35 reported that the urinary control obtained at operation had remained complete, while the remaining 12 reported that although control of the urine had been good following the operative correction the incontinence had gradually returned in greater or lesser degree after about a half

struation time but now there was a constant discomfort, especially marked during the menstrual period and predominating on the left side. There was a large tumor in the region of the left ovary which had pushed the uterus over to the right and a smaller mass in the right ovarian region. At operation the ovaries were unrecognizable their place having been taken by tumor masses showing the characteristics of endometriosis. Subtotal hysterectomy and bilateral ovariectomy brought complete relief however some months later the hypogastric pains recurred predominating on the left side they were accompanied by some bleeding. These attacks occurred at the habitual time for menstruation. Examination disclosed a tender mass, the size of a large walnut in the left cul-de-sac. Testosterone (acetestosterone) was started and when 520 mgm. had been administered the mass had diminished to half its original size. The treatment was continued at the rate of 100 mgm. per month and after 2 months no trace of the mass could be found. There was now only a half day's bleeding at the menstrual period and some heaviness in the left leg. Some months later there was no more bleeding and the patient was free of pain.

Histologic diagnosis of the original tumor was typical ovarian endometriosis and the author believes that the recurrent tumor was of the same character. He believes that the efficacy of the male hormone in these cases is established nevertheless there are 3 other methods of treating endometriosis (conservative ablation of the tumor itself, castration and irradiation therapy) and these may be used alone or in combination to fit the exigencies of the individual case.

JOHN W. BREXMAN M.D.

The Surgical Aspects of Endometriosis (Aspetti chirurgici dell'endometriosi) EMILIO MUMFORD. *Arch Ital Chir.* 1947 69 47

Adjunctive to and as motivation for an extensive review of the medical literature with regard to the pathogenesis of endometriosis the author reports 4 cases from his own personal experience.

The first case was that of a 45 year old pluriparous woman who underwent a subtotal hysterectomy for a voluminous fibromyoma of the uterus. During the course of the operation a horseshoe shaped new growth partially encircling the sigmoid colon was uncovered and extirpated together with the involved section of the gut. This new growth consisted of a complex of tubular glandlike structures containing mucus and blood enclosed in a stroma resembling the cell rich stroma of the endometrium and lined with cylindrical epithelium in one or more layers. The tumor growth had invaded the serosa, the subserous connective tissues and the muscularis but had nowhere involved the mucosa of the colon. In this case the theory of Sampson—with reference to an endometrial transplant by way of a reflux of menstrual blood through the tube—as favored by the presence of a fibromyoma of the uterus and a propitious hormonal milieu—seems to find its ideal application.

The second patient a 37 year old multiparous woman had suffered more or less since girlhood from a severe anemizing menorrhoea and a progressive condition of constipation which for the past 8 months had at times amounted to a subocclusion. At operation a firm tumor mass the size of a hen's egg was found to be firmly adherent to the rectum on one side and to the left side of the vaginal vault on the other. The uterus was removed with 2 cm. of the vaginal wall and about 4 cm. of the rectum together with the tumor mass. Here again the histological examination disclosed the characteristics of an endometrial tumor involving the posterior wall of the vagina, the posterior muscular wall of the uterus and the serous and muscular layers of the rectum but nowhere involving the mucosa itself. This condition is explained as a simple spread of the process by contiguity from the original lesions in the genital organs to the rectum, the impetus to proliferation being furnished by the hormonal instability of the period immediately preceding the menopause.

The third case was that of a 40 year old multipara in whom an endometriosis of the myometrium—the so-called endometriosis interna—was discovered in a uterus which had been removed en masse with a right sided pyosalpinx and a left-sided hydrosalpinx. It is mentioned as a possible example of the so-called phlogistic impetus to endometrial development.

The fourth case was that of a 40 year old woman who had never been pregnant. The appendix had been removed when she was 8 years old and the wound had drained and suppurred for a considerable period before healing. Thereafter for 32 years the cicatrix had shown nothing abnormal then it began to pain during the menstrual periods, and later opened and discharged a dark-colored liquid. Finally a bluish black nodule appeared on the outside and continued to increase in size. The nodule, together with about 6 cm. of the scar was excised and histologic examination disclosed the usual complex of apparently interconnected glandlike structures embedded in the typical cell rich stroma of endometriosis. However in addition to the usual picture of endometriosis there was a remarkable finding in this case which the author believes has not thus far been described. This consisted of areas of what appeared to be invasions of young blood vessels and sinuses lying in a loose delicate stroma and lined with the usual flat layer of endothelium. Closely juxtaposed to these areas were others with other blood-containing vessels and sinuses, the lining membrane of which had become thickened until in places the carpeting cells became cubical or even cylindrical in one or more layers, just as in the glandlike structures of endometriosis. In these areas the delicate supporting stroma of loose connective tissue became denser more cell rich and protruded into the lumina in the form of papillary elevations typical of endometriosis. The author did not actually find any intercommunications between the young blood vessels and the mature endometrioid structures, although they often lay side by side and their general

The trigonal muscle smooths down the mucous membrane of the internal orifice but alone does not open the internal orifice and posterior urethra. This action, the author believes, is accomplished mainly by a voluntary downward pull of the anterior perineal muscle.

When the internal orifice sags, most frequently as a result of childbirth damage, although this condition may be congenital or neurogenic in etiology, then a sudden impact such as is caused by a cough or sneeze may cause leakage (stress incontinence).

Residual urine may be found 'back' of urethroceles as a result of imperfect action of the internal orifice region, a sag of the bladder greater than that of the internal orifice, or a spastic internal orifice, with or without a sagging bladder base. Residual urine adds to the frequency of stress incontinence.

A cystourethrocele results entirely from the lowered sagging bladder and internal orifice. Both move forward when the patient voids.

Cytoscopic diathermy to the areas of hyperplastic urethritis and/or dilatation of the internal orifice, or possibly transurethral resection of a glandular hyperplasia or scar contracture at the internal orifice, may give satisfactory symptomatic relief.

In nearly every instance, surgical repair should be performed anteriorly from the urethral meatus and should include repair and strengthening of the pelvic floor.

FARDEAR A. LLOYD, M.D.

The Treatment of Vesicovaginal Fistula; Presentation of 4 Cases Successfully Operated upon (Tratamiento de la fístula vesicovaginal, presentación de cuatro casos operados con éxito). R. VARGAS ZALAZAR. *Arch. Soc. cir. hisp.* Santiago, 1947. 7: 487.

After the patient has been carefully examined to ascertain the localization, extent, and condition of the fistula, the local and urinary infection must be completely eradicated before operation is attempted. During this preliminary treatment, the necessary vesical rest is obtained by suction with an appropriate apparatus, and the general condition of the patient is improved by transfusions and rest. The vaginal route of operation is used for low fistulas which are located in the vesical neck or trigone; for those which are located behind the trigone he uses the transvesical route. In general, he prefers to operate through the vagina because it is easier and the patient is exposed to less shock. The patient is placed in a ventral decubitus position for the vaginal route of operation and in a dorsal decubitus position for the transvesical route.

An incision is made around the fistula, about 0.25 cm. from its border, including the whole vesical or vaginal wall, depending on the route of operation. The two walls are separated by cutting with curved scissors. Immediately the deep plane which carries the small collar of the fistula is seen to retract. This plane is closed with U sutures which invaginate the fistula toward the vagina when the transvesical route is used, and toward the bladder when the vagi-

nal route is used. The suture material is chromic catgut. When the deep plane is completely closed, the edges of the superficial plane are united with perforating U sutures which insure that these edges remain invaginated toward the bladder in the transvesical operation and toward the vagina in the vaginal operation, thus guaranteeing good healing. An indwelling catheter is then fixed with catgut to the labia minora and the suction apparatus is installed for 2 weeks. When the hypogastric route is used, an obstructed Pezzer catheter is also installed to make sure that the apparatus functions well. Sulfonamides and penicillin are given from 2 days before operation to a few days after it.

Four patients were successfully treated by this method. The vesical approach was used in 3 cases and the vaginal approach in 1 case.

RICHARD KIRKEE, M.D.

The Prophylactic Treatment of Operative Gynecological Infections in the Course of Radium Therapy (Sul trattamento profilattico delle infezioni operatorie ginecologiche e delle infezioni in corso di radioterapia). GUINETTE VALLER. *Ginecologia*, Tor. 947: 3: 353.

The author discusses the criteria for the choosing of methods of immunity, chemotherapy, and antibiotics in the prophylactic treatment of operative gynecological infections.

The injection of foreign protein increases the number of leucocytes and phagocytes. Its action is also on the formation of antibodies and the stimulation of the reticuloendothelial system.

The author advocates sulfonamides prophylactically with the following procedure of administration: from 6 to 8 gm. of the drug are given by mouth 24 hours before surgery. On the day of surgery 5 c.c. of a 50 per cent solution are given intravenously. After surgery 6 to 9 gm. of the drug are given every 4 hours until the patient is out of danger or the sulfonamide blood level reaches 15 mgm. With this plan good results were obtained.

Although the author has not had much experience with the prophylactic use of penicillin he cites the following advantages of penicillin over sulfonamides: (1) quick bacteriostatic action, (2) absence of secondary toxic actions which allows a larger dose and prolonged treatment even in poor operative risks, and (3) the greater diffusibility of penicillin makes possible its action on sulfonamide-resistant organisms.

ARTHUR F. CIPOLLA, M.D.

Recurrence of a Bilateral Ovarian Endometriosis Following Castration. Favorable Action of Testosterone (Récidive d'une endométriose ovarienne bilatérale après castration. Action favorable de la testostérone). EMILE DELANNOY. *Gyn. obs.*, Par. 947: 46: 533.

A 42 year old woman, who had never borne children but who had had an abortion at 20 years of age, had been suffering from hypogastric pains for about 15 years. At first the pains appeared only at men-

struation time but now there was a constant discomfort, especially marked during the menstrual period and predominating on the left side. There was a large tumor in the region of the left ovary which had pushed the uterus over to the right and a smaller mass in the right ovarian region. At operation the ovaries were unrecognizable their place having been taken by tumor masses showing the characteristics of endometriosis. Subtotal hysterectomy and bilateral ovariectomy brought complete relief however some months later the hypogastric pains recurred predominating on the left side they were accompanied by some bleeding. These attacks occurred at the habitual time for menstruation. Examination disclosed a tender mass, the size of a large walnut in the left cul-de-sac. Testosterone (acetosterandryl) was started and when 550 mgm. had been administered the mass had diminished to half its original size. The treatment was continued at the rate of 100 mgm. per month and after 3 months no trace of the mass could be found. There was now only a half day's bleeding at the menstrual period and some heaviness in the left leg. Some months later there was no more bleeding and the patient was free of pain.

Histologic diagnosis of the original tumor was typical ovarian endometriosis and the author believes that the recurrent tumor was of the same character. He believes that the efficacy of the male hormone in these cases is established nevertheless there are 3 other methods of treating endometriosis (conservative ablation of the tumor itself, castration and irradiation therapy) and these may be used alone or in combination to fit the exigencies of the individual case. JOHN W. BRENNAN, M.D.

The Surgical Aspects of Endometriosis (Aspetti chirurgici dell'endometriosi) ENRICO MURTONI *Arch Ital chir* 1947 69 47

Adjunctive to and as motivation for an extensive review of the medical literature with regard to the pathogenesis of endometriosis the author reports 4 cases from his own personal experience.

The first case was that of a 45 year old pluriparous woman who underwent a subtotal hysterectomy for a voluminous fibromyoma of the uterus. During the course of the operation a horseshoe-shaped new growth partially encircling the sigmoid colon was uncovered and extirpated together with the involved section of the gut. Thereafter for 32 years the cicatrix had shown nothing abnormal then it began to pain during the menstrual periods, and later opened and discharged a dark-colored liquid. Finally a bluish black nodule appeared on the oot side and continued to increase in size. The nodule, together with about 6 cm. of the scar, was excised and histologic examination disclosed the usual complex of apparently interconnected glandlike structures embedded in the typical cell rich stroma of endometriosis. However in addition to the usual picture of endometriosis there was a remarkable finding in this case which the author believes has not thus far been described. This consisted of areas of what appeared to be invasions of young blood vessels and sinuses lying in a loose delicate stroma and lined with the usual flat layer of endothelium. Closely juxta-posed in these areas were others with other blood-containing vessels and sinuses, the lining membrane of which had become thickened until in places the carpeting cells became cubical or even cylindrical in one or more layers, just as in the glandlike structures of endometriosis. In these areas the delicate supporting stroma of loose connective tissue became denser, more cell rich and protruded into the lumina in the form of papillary elevations typical of endometriosis. The author did not actually find any intercommunications between the young blood vessels and the mature endometrioid structures, although they often lay side by side and their general

picture suggested such communication therefore he does not attempt to maintain that they are a substantiation of the metaplasia theory of R. Meyer. He merely presents several figures and allows others to draw their own conclusions. He hopes that in this manner they will be attracted to contribute to and attempt to further elucidate this question.

JOHN W. BRIDGMAN, M.D.

The Role of Celioscopy in the Diagnosis and Treatment of Sterility and Ectopic Pregnancy (La place d la celioscopie dans le diagnostic et le traitement des stérilités et des grossesses ectopiques) RAOUL PALMER and IRENE JACOBOWITZ. *Rev. fr. gyn. obs.* 1947 43: 3.

The authors have performed about 200 celioscopies without a mishap and with only 11 total or partial failures. The present report is based on the performance of 78 celioscopies during the period from July 1945 to July 1946.

The following technique is applied:

1. The cervix is grasped by a tenaculum and if no uterine pregnancy is suspected a cannula for insufflation is introduced into the uterus. This permits elevation and movement of the uterus to a position of anteversion, to open the retrouterine space for exploration of the tubes and ovaries. At the same time, this measure permits of uterotubal insufflation or salpingography in the course of the celioscopy.

2. A special needle is pushed through the abdominal wall in the left hypochondrium to produce a pneumoperitoneum as preparation for a paracentesis with a trocar.

3. Under local anesthesia, a small skin incision is made 4 cm. below the umbilicus; a trocar is introduced through this incision and the stylet is replaced by the peritoneoscope.

4. The patient is placed in Trendelenburg position to rid the pelvic cavity of intestinal loops and an

assistant manipulates the uterine cannula to elevate and tilt the uterus anteriorly. Now the uterus, the adnexa, the cul-de-sac and the neighboring organs can be explored.

5. If adhesions hinder the view or have to be severed for therapeutic purposes, a second trocar can be introduced to admit a galvanocautery for cutting the adhesions.

6. At this stage insufflation of the tubes or hysterosalpingography can be added to the celioscopy to verify the permeability of the tubes.

Conditions which can be recognized by celioscopy include normal pregnancy, uterine fibroids, retro-uterine adhesions which prevent the correction of a retroflexion pathology of the ovary (cysts, endometriosis, periovaritis), tubal pregnancy, hydrosalpinx, tuberculosis of the tubes, and pathology in the cul-de-sac. The neighboring organs (bladder, pelvic colon, cecum and appendix) also may be visualized and investigated; however the exploration of the appendix is often difficult and should not be enforced.

In cases of sterility celioscopy is indicated only as a last resource. Examination of the spermatozoa, of the cervical mucus, and salpingography should precede it. There is, however, one exception to this rule. If a palpable mass of the adnexa is present, insufflation or salpingography are contraindicated because they may cause a flareup of an old pyosalpinx. Also if there is a suspicion of genital tuberculosis, no insufflation should be attempted. In these cases, celioscopy should be done first, and only if an inflammatory lesion has been ruled out should the permeability of the tube be tested by means of salpingography.

Ectopic pregnancy reveals an unmistakable picture in celioscopy and in doubtful cases, can be easily differentiated from other conditions with similar clinical symptoms, especially a ruptured corpus luteum cyst.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Preservation of the Threatened Pregnancy with Particular Reference to the Use of Diethylstilbestrol
GORDON ROSENBLUM and EUGENE MELINKOFF
West. J. Surg. 1947 55 597

One of the greatest obstetrical problems confronting the clinician today is that of abortion and premature labor. It has been estimated that from 20 to 30 per cent of human pregnancies terminate by spontaneous or induced abortion. This problem is made even more profound when the therapeutic measures available are surveyed. With this in mind the authors have analyzed the existing forms of therapy which are available today.

1. The conservative school of therapy consists essentially of bed rest and sedation. This form of therapy is difficult to evaluate because of the lack of control studies, but the general tendency is to minimize the value of rest in the prevention of abortion.

2. The vitamin school of therapy consists essentially of the administration of vitamin E. Successful results have been reported in as high as 80 per cent of treated patients. In general there is no real agreement as to its value and the prevailing thought is to minimize its value.

3. The endocrine school of therapy has high regard for thyroid as a therapeutic agent but thyroid cannot be evaluated thoroughly because of the lack of control studies. The results of steroid progestogens are variable and figures pertaining to its use, with success vary from 18 to 90 per cent; some observers have claimed 67 per cent success with steroid progestogens and estrogens, but here again there is no unanimity of opinion. Steroid estrogens alone have been used in the treatment of pre-eclampsia and diabetes in pregnancy but evaluation is not possible because of the lack of controls.

The authors present a series of 95 cases of threatened abortion, habitual abortion, and threatened premature labor treated with bed rest, sedation with barbiturates and diethylstilbestrol 5 to 200 mgm daily. The following statistical results were obtained.

Of 81 cases of threatened abortion, 71 patients carried to term, 10 cases of habitual abortion were encountered; of these 5 carried to term, there were 4 patients with threatened premature labor, 3 of whom carried to term. These results are more favorable than any which the authors have been able to achieve with other forms of therapy.

The toxic effects were mild nausea and pigmentation of linea nigra, congestion of the breasts and darkening of the areolae of the nipples.

Sixteen of 18 patients who had been sterile, carried to term.

J. ROBERT WILSON, M.D.

The Late Toxemia of Pregnancy: The Number One Obstetrical Problem of the South. ROBERT A. ROSS.
Am. J. Obs., 1947 54-733

The problem of the 'ill-fed, ill-clothed and ill-housed' is not new in the South nor is the menace of the toxemia of pregnancy. That these apparently diverse statements are related and pertinent is not too difficult to demonstrate. With no sharp demarcation, there are 3 dietary groups of patients in North Carolina: (1) the intelligent, economically capable, (2) the fairly co-operative adequately nourished and (3) the uninformed, improperly nourished, medically inarticulate group of patients. Toxemia is rarely found in the first two but it is the prime factor in maternal mortality in the last.

The author analyzes 11,000 deliveries in Duke Hospital, Durham, North Carolina, from 1931 to 1946. His criteria for the eclamptic state are blood pressure 160/100, albuminuria, increased blood urea acid and lowered CO₂ combining power associated with other usual findings. Included in this group were 303 patients with convulsions and 106 patients without convulsions. Four of the patients in the latter group who later developed convulsions died. The percentage of deaths in the total group of eclamptic patients was 11.1 per cent, and the percentage of deaths among those with convulsions was 15.2 per cent. Nearly 1,500 patients had 'other toxemia of pregnancy' (hypertensive and cardiovascular renal conditions) and the total mortality in this group was 3.7 per cent. The total number of deaths from 'late toxemia' was 80 (4.5%). These 80 deaths represent 38.2 per cent of all of the deaths in obstetric patients.

The lack of prenatal care in this series of cases, as in other reported series, stands out. Thirty-five of the patients who were in the eclamptic state when first seen died. Of these 19 had not seen a doctor during the pregnancy until convulsions occurred; 5 patients had made one visit to a doctor, none had made three visits; 1 had 'fair' prenatal care and only 1 had care that was good.

On checking the localities from which the toxemic patients had been referred and on reviewing the State morbidity and mortality statistics it was found that the areas in which eclampsia occurred most often were the same areas in which a large percentage of the cases of pellagra and similar diseases occurred. The patients admitted in eclamptic convulsions came from the same group who subsisted on a diet similar to that of pellagrins. The diet is grossly deficient in all the vitamins, especially vitamins A, C and D as well as in the minerals and proteins. In this group the dietary very likely had been deficient both in the quantitative and qualitative aspects.

The author discusses the general purposeful efforts being made toward better prenatal care throughout this area.
JOHN R. WOLFF, M.D.

Fatal Eclampsia. A Clinical and Anatomic Correlation Study. GEORGE T. C. WAY. *Am J Obst* 1947 54: 928.

The author presents a summary of all fatal cases of eclampsia which were examined at autopsy in the Department of Pathology, Duke Hospital, Durham, North Carolina, during the period from 1930 to 1946. The clinical histories and postmortem findings are correlated. An attempt is made to correlate the observed lesions with some current hypotheses concerning the pathogenesis of eclampsia.

By summarizing the essential clinical aspects of these fatal cases of eclampsia, the author creates a composite picture of the average patient.

If a primipara, the patient is about 19 years of age, and has had at least one convulsion prior to admission. During the few days or weeks preceding admission she has experienced increasingly severe headaches and edema. She may also complain of one of the three following symptoms: recent nausea and vomiting, visual disturbances, or abdominal pain. Physical examination reveals that she has hypertension and generalized edema, and is in a comatose condition. Tachycardia and pulmonary edema may or may not be present.

If a multiparous patient, she is about 30 years of age and has had the signs and symptoms of pre-eclamptic toxemia during a previous pregnancy. There is one chance in three that she has had a previous attack of eclampsia. She, too, is comatose and demonstrates hypertension and edema. In all probability she has had convulsions prior to admission.

Both patients will demonstrate a slight increase in blood nonprotein nitrogen and a definite increase in blood uric acid. Total plasma proteins will be reduced, and the albumin-globulin ratio will be markedly reduced. Death will ensue in about 2 days.

Anatomic study reveals the liver to be the seat of a important pathologic change. The lesion most frequently encountered is a focal hyaline or fibrinoid necrosis of the liver cells, usually but not necessarily in the periportal areas and usually of recent origin, with or without hemorrhage.

Renal lesions have been divided into three stages which represent steps in the development of permanent renal change: first stage lesions with glomerular but no arteriolar alterations were typical in 33 per cent of the cases; second stage lesions characterized by thickening of the arteriolar wall, were observed in 48 per cent of the cases; third stage lesions similar to arteriolonephrosclerosis characterized 18 per cent.

Eleven patients demonstrated hemorrhage and necrosis in the adrenals. In 5 of these the condition was classified as severe. An attempt has been made to correlate these lesions with vascular collapse prior to death.

Additional lesions were found, as follows: pneumonia, focal necrosis of the myocardium, pancreas

and brain, acute endometritis, cerebral hemorrhage, cystitis, acute mastitis, cerebral arteritis and arteriolitis.
JOHN R. WOLFF, M.D.

LABOR AND ITS COMPLICATIONS

Low Cesarean Section: the Treatment of Choice in Placenta Previa (La césarienne basse; traitement chirurgical de choix du placenta prævia). J. N. MULLER. *Rev. f. gyn. obs.*, 1947 43: 236.

The author reports a series of 199 cases of placenta previa which were observed during the periods from 1919 to 1939 and from 1946 to 1947. Fifty of the patients in this series were treated by low cesarean section, and only 1—a patient who had lost a great amount of blood before the operation—died on the operating table.

The author presents a detailed statistical analysis of these cases which shows that the maternal mortality as well as the fetal mortality rate is lowered considerably by low transverse cesarean section as compared with other obstetrical procedures such as rupture of the membranes, podalic version, and bag induction.
WILHELM M. SCHMIDT, M.D.

An Analysis of 416 Consecutive Cesarean Sections. RICHARD B. NICHOLS and WILLIAM C. ANDREWS. *Am. J. Obst* 1947 54: 79.

The authors analyze a consecutive series of 416 cesarean sections done during a 12 year period from January 1, 1935 through December 31, 1946. The cases are considered in two groups. The first 275 in number included patients who came directly as private patients, not referred by any physician, or who were referred early in pregnancy and so were given prenatal care by the authors. The second group of 141 patients were referred either late in pregnancy or in labor or the emergency had already existed when first seen. The authors were not able to study the majority of the cases in this group before the advent of labor.

The purpose of this article was to evaluate the results, insofar as they applied to the authors regarding mortality, morbidity and fetal deaths.

In regard to indications, disproportion (in 211 cases) provided the largest number both in the personal group (138) and in the referred group (73). The disproportion was determined by roentgenography and the various degrees of disproportion were ascertained, including contracted midpelvis and outlet. Roentgenograms were used extensively in estimating the maturity of the fetus, the location of the placenta, the number of babies, and in detecting malformation of the fetal skeleton and in some cases the position of the presenting part. The authors believe that this plan has eliminated severe complications associated with prolonged labor, uterine inertia, and hemorrhage, which have contributed so largely to both mortality and morbidity of the mother and death of the child.

Placenta previa and premature separation of the placenta furnished the indication for cesarean section

in 61 cases, although all these cases were not sectioned. All patients with central placenta previa were sectioned. Some patients with marginal and lateral placenta previa were sectioned because of the amount of bleeding and the condition of the cervix. A similar plan for premature separation of the placenta was used.

Eclampsia, pre-eclampsia and toxemia. A small group (12) of patients with these conditions was delivered by cesarean section. Eclampsia and/or pre-eclampsia were not considered indications for section, rather cesarean section was regarded as the method of terminating the pregnancy in selected cases and then only when they were adequately treated. 94.5 per cent of the sections were cervical in type.

Fetal mortality. There was an uncorrected fetal mortality of 5.8 per cent (10) in the personal group and of 1.4 per cent (20) in the referred group.

Maternal mortality. In 3,035 deliveries performed during this 12 year period there were 9 maternal deaths 6 of which were associated with cesarean section. Of the 9 deaths 2 were in the personal group and 7 were in the referred group. Of the 6 associated with cesarean section, 4 were in the referred group. The deaths associated with cesarean section include 2 postmortem sections both in the referred group which are included for completeness of review. The first mortality in the personal group was due to sepsis and occurred before the advent of sulfonamides, penicillin or other antibiotics. The second mortality in this group was due to pulmonary embolism, which the authors believe is a surgical risk faced by any patient undergoing surgery. In the referred group all 4 deaths occurred in women who had no prenatal care. They were primarily pre-eclamptic or eclamptic, although 1 died secondarily of hemorrhage.

The authors conclude that cesarean section per se is not the chief cause of maternal death as it has been thought to be, but rather that the obstetric complications cause death in most cases this applies in general to the fetus. It is also observed that in obstetric patients who are cared for by proper prenatal study and individualization the maternal and fetal mortality is definitely reduced.

JOHN R. WOLFF M D

PUERPERIUM AND ITS COMPLICATIONS

Postabortion Phlegmonous Gangrene of the Uterine Cervix (Phlegmon gangræneux post abortum du col utérin). M. MAYER, A. GRAMON and BEAUCHAMP. *Gyn. obsit. Par.*, 1947 46 537

A 32 year old woman had been pregnant for 2½ months when attempts were made to produce artificial interruption. Seventy two hours after the last attempt, chloroform was administered and the uterus was cleaned out digitally and with a large blunt curette. At this time the patient had fever and the body of the uterus was enlarged and tender but the cervix seemed perfectly normal. Five units of posterior hypophyseal preparation were injected into the

anterior lip. Two days later despite absolute bed rest, an icebag to the abdomen and sulfonamides the patient was extremely ill and the uterine cervix had increased in size so that it apparently filled the entire lower portion of the pelvic cavity. The abdomen was opened and the uterus removed, but the patient did not rally from the operation.

A few cubic centimeters of fetid fluid were found in the peritoneal cavity which on culture yielded the *Clostridium perfringens* and a streptococcus. Macroscopically, the removed specimen presented what appeared to be a practically normal uterine corpus perched upon an enormously enlarged cervix. The cervical tissues presented a lardaceous appearance and seemed to be shot through with small cavities filled with clot and bacteria, exuding a fetid fluid. The mucosa of the cervical canal appeared to be gangrenous. Microscopically the mass of cervical tissue was found to be composed of amorphous filaments staining blue with hematoxylin. Most of the cavities were lined with endothelium and contained deteriorating red blood corpuscles and masses of bacteria.

The authors believe that the infection of the hypophyseal preparation played an essential role in the development of this condition, and they recommend that in future this drug should not be used following curettage in this manner particularly in cases in which the ovum as a whole or in part has remained in the dilated gaping cervix for a more or less prolonged period of time. JOHN W. BRENNAN M D

Rupture of Purulent Puerperal Ovaritis (La rupture des ovaires purpures puerpérales). P. TAILLAT and A. NORRIS. *Gyn. obsit. Par.* 1947 46 161

Eight days after a spontaneous abortion in the fourth month of her second pregnancy a patient suddenly developed hyperpyrexia, violent pains and boardlike rigidity of the abdominal wall. Laparotomy revealed a ruptured abscess of the right ovary and the patient died one day after intervention.

The authors report 3 similar cases from the modern or more recent literature and 12 cases from older literature. All but one of these patients died of generalized peritonitis due to ruptured ovarian abscess following abortion or delivery. The only patient on record who survived was a quadripara 42 years of age who was operated on 4 months after delivery for an alleged appendiceal abscess. The appendix was not found at that time and the abscess was drained by a rubber tube. As the sinus persisted a second operation was performed 6 months later and an ovarian abscess the size of a tangerine was found and removed.

The clinical course and pathogenesis are discussed briefly. Invasion of the ovary may occur by hematogenous or lymphatic spread, or from the tube. The site of the abscess is usually in the center of the organ, the organisms causing the abscess being mostly streptococci. The characteristic clinical picture is low grade fever following abortion or delivery. After a free interval of longer or shorter duration, a second

episode develops with high fever, abdominal pains, metrorrhagia, and leucorrhoea. The ovary may rupture into one of the neighboring organs (rectum, vagina, or bladder) or into the peritoneal cavity, rupture into the rectum is of comparatively good prognosis. Rupture into the peritoneal cavity led to fatal generalized peritonitis in all cases on record.

WILHELM M. SOLMITS, M.D.

Paralysis of the External Popliteal (Common Peroneal) Branch of the Sciatic Nerve in the Puerperium (*Les paralysies du sciatique poplite externe dans le post partum*). PAUL TRILLAT and MARCEL DUMONT. *Gyn. et Obst. Par.* 1947 46 4 3.

The authors report 6 cases of peroneal nerve palsy observed at the Obstetrical Clinic of Lyon, France in recently delivered women.

They reviewed the anatomy of the sacral plexus and its relationship to the bony pelvis. The 6 cases were discussed in some detail. Four of the patients were primiparas and 2 were multiparas. Three of the patients were delivered by midforceps. In 2 of the spontaneous deliveries the infants were large (4,000 gm. and 3,840 gm.) and both of the mothers had slight pelvic contraction. One patient, a para, with a history of 5 previous normal deliveries, had a spontaneous delivery of a 3,000 gm. baby through a normal pelvis, but nevertheless developed paralysis.

The authors discussed the hypothesis of Morgan and Thomson who attributed the paralysis to direct compression of the peroneal nerve while the patient was in the lithotomy position during delivery. As some of the patients in the cases discussed by Trillat and Dumont were delivered spontaneously and were never placed on a gynecologic table the authors rejected this mechanism as the sole cause of nerve compression.

They emphasized several interesting clinical points. All of their patients had definite pain referred to the distribution of the peroneal nerve. At the time of delivery the patients complained of cramps, formication or burning, beginning in the calf and radiating to the toes. In one case, severe pain was felt in the buttocks. In all of their cases the pain was unilateral. The paralysis was frequently not observed until the patient began to walk and foot drop was noted. Spontaneous cure usually occurred in 2 or 3 weeks. One patient had paralysis for 6 months, and some patients have been reported as having paralysis which persisted for several years.

The authors concluded that paralysis of the external popliteal branch (common peroneal) of the sciatic nerve occurring in women recently delivered are probably the result of compression of this nerve inside the pelvis when there is a high division of the sciatic nerve. The typical case is that of a primigravida undergoing a difficult delivery, in the course of which it is necessary to apply forceps on a head arrested at the superior strait or in the hollow of the pelvis in a posterior occipital presentation. The authors think that vitamin B deficiency predisposes to such paralysis.

CRAIG W. MECKLER, M.D.

NEWBORN

A Premature Survival Index and the Conduct of Premature Labor. A. LOUIS DIFFER, HERMAN W. JOHNSON and J. L. CONDELLINOT. *Am. J. Obst.*, 1947 54: 1004.

There is today no unanimity of opinion as to precisely what constitutes a 'premature infant,' no standard being universally accepted. The authors review basic definitions for prematurity and for abortion. Various individual criteria in common use for the diagnosis of prematurity are discussed and reasons given for their inaccuracies when employed separately. A 5 point premature survival index is offered as a means of overcoming inaccuracies in individual criteria and is applied to 23 premature newborns.

The index was obtained by adding gestation in weeks, weight in ounces, crown-heel length in inches, head circumference in inches, and chest circumference in inches, and then dividing the total by five. This resulted in indexes ranging from 19.2 to 25.7 for the infants discussed. The authors suggest that a combination of a larger number of factors of the small premature infant should produce less inaccuracy in the diagnosis of prematurity and in prognosticating the probable outcome than has thus far been possible with any of these factors used alone. The assumption is that the inaccuracies in single factors will tend to be equalized when combined with each other. The authors believe that after further experience they will be able to say that every premature infant born alive in good condition with an index of at least 21 should be reared. Those with an index below this figure need not be considered hopeless. It should be possible to determine probable survival rates for each group below this level, in the absence of congenital anomalies, obstetric accidents, individual maternal variations, and maternal diseases.

Suggestions for the obstetrician's contribution in reducing the premature infant mortality rate are given. These include avoidance of analgesia after the onset of true labor in the period of prematurity, the use of local or regional anesthesia for premature delivery, preservation of the integrity of the fetal membranes through the second stage of labor, maintenance of the maternal-fetal circulation as long as possible, and the prophylactic use of chemotherapy in premature labor.

JAMES R. WOLFE, M.D.

Low Maternal Mortality with Persistence of Hemorrhage as the Chief Cause of Death; An Analysis of Puerperal Deaths in Brooklyn during 1946. CHARLES A. GORDON. *Am. J. Obst.*, 1947 54: 1 38.

In 1946 there were 57 deaths in Brooklyn which were assigned to puerperal causes by the Bureau of Records and Statistics of the Department of Health of the City of New York to give a maternal death rate of 8.7 per 10,000 live births.

Death was due to ectopic pregnancy in 2 cases, because of failure of diagnosis. In 4 cases a abortion had

been induced with perforation of the uterus and in fetal injury in 2 cases in 2 other cases in which hemorrhage was profuse for several hours death was finally due to infection.

Officially 12 deaths were considered due to toxemia 3 more were found in the infection group and 1 death in the abortion group. Prenatal care was inadequate in all but 2 cases. In 3 cases hemorrhage was said to have been considerable although death was due to eclampsia. Convulsions occurred in 9 cases. Cesarean section was performed 5 times in 3 cases after convulsions.

Included in the infection group of 12 cases were 3 deaths due to cardiac disease since death had been attributed to pulmonary embolism. Altogether embolism was mentioned in 10 of the 12 cases assigned to infection. A case of eclampsia was included with 3 cases of death shortly after delivery in which dyspnea, paroxysmal cough and cyanosis point to anesthetic as the cause of death. In 2 cases clinical embolism occurred on the third and fifth days in women who were up and about.

Only 8 deaths were formally assigned to hemiarthrectomy. In 2 of the 3 cases of postpartum hemorrhage hysterectomy was performed after other measures had failed. Hemorrhage was the actual cause of death however in 6 cases otherwise tabulated as abruptio placentae rupture of the uterus and probable rupture of the uterus. As much as 8 units of plasma were given to one patient before blood was procured just prior to hysterectomy. In another case of postpartum hemorrhage bleeding continued for 3 hours in bed while 4 units of plasma were administered. The uterus was continuously massaged but not explored. Hemorrhage was the actual cause of peripartal death in 35 per cent of the 57 cases.

Cesarean section was associated with death in 14 of the 57 cases. For the last 10 years approximately one third of the maternal deaths exclusive of those early in pregnancy have been associated with cesarean section. Not only do the indications for this procedure need close examination but a high standard of performance is required with attention to every detail.

It is not possible to learn the true importance of anesthesia from the statistics of maternal death. Even though death is stated to have been directly due to aspiration of vomitus anesthesia is not tabulated as a cause of death. Anesthesia was an important cause of death in Brooklyn in 1946. Deaths may be readily separated into three groups as due to the toxic action of the anesthetic drug, to aspiration of phlegm, and to atelectasis, whether from aspiration or not. The records of 8 cases are given.

JOHN R. WOLFF M.D.

Respiratory Difficulties of Infants at Birth (Les troubles respiratoires de l'enfant à la naissance) P. LANTIER, J. L. RIBADEAU DUMAS, HÉRAUX and J. DEBRAY. *Jr méd chir thorac.* 1947; 1: 230.

The authors discuss the causes of respiratory failure in infants during childbirth. The mechanism of

intrauterine aspiration of amniotic fluid and of the establishment of normal respiration at birth is reviewed. Pneumographic findings and roentgenographs of fetuses with normal respirations and of fetuses with bronchial obstruction are shown.

In cases of persistent bronchial obstruction the fetus makes desperate respiratory efforts. The pulmonary effects are congestion bronchoalveolar distention bullous emphysema hemorrhages and arterial and venous thromboses.

Pneumothorax of the newborn was described by Runge in 1878. Such pneumothorax is not rare in the authors' experience. Difficult delivery or rupture of a small pulmonary abscess into the pleural cavity is the usual cause. The diagnosis is often missed because dyspnea and cyanosis are commonly observed in slow labors. Radiologic examination readily discloses the existence of pneumothorax but must not be confused with aeration of the clear zone of the normal lung. These pneumothoraces are often not noticed and their prognosis is good.

The term *angioalveolitis* is applied to those severe respiratory conditions characterized by such vascular effects as dilatation of the vessels edema of the endothelium. These conditions associated with cerebral hemorrhages and multiple visceral hemorrhages were frequently found in stillborn infants.

Pulmonary infections of the fetus during birth may be the result of aspiration of septic fluids or septicaemia. Bacterial invasion is favored by the length of labor after rupture of the membranes. Contamination of the ovum with aspiration of infected amniotic fluid is mentioned as a rare occurrence. Infection of the amniotic sac occurs by the ascending route from the vagina. Pathologic conditions in the vagina produce rhinopharyngitis congenital otitis and bronchopneumonia which appear at birth or in the days following birth.

The infection sometimes begins peripherally, for example as pulmonary lesions secondary to umbilical infection. Once the authors' attention had been attracted to these conditions, they were found much more frequently and at autopsy pulmonary lesions were revealed in 75 per cent of the cases. The lungs react differently to infection via the bronchi and by way of the blood.

Infection by aspiration of septic liquids is favored by slow and lengthy labor. It occurs by aspiration of amniotic fluid at the moment of birth. Examination of the lungs of stillborn infants whose mothers had long infected labors revealed pulmonary congestion with masses of bacteria in the bronchi and alveoli. There was no doubt that the infection had taken place by way of the respiratory tract. It is a state of bacterial invasion and of congestion.

It is possible to find typical bronchopneumonia in the fetus and in the newborn infant. The lesions are variable pneumonic in type with congestion, edema and hemorrhage. Usually the infant is born dead but sometimes it survives. The symptoms may be

slight or very marked. Radiography gives valuable information in such cases. The prognosis is usually poor but some infants have been saved by penicillin therapy. The pulmonary lesion may result in the formation of little abscesses, the rupture of which into the pleura causes pneumothorax and pyothorax. Acute obstruction of the bronchi results in edema and hemorrhage.

Infection of the lungs by way of the blood stream may take several forms. Purely congestive types occur without bacteria. Septicemic lesions with bacterial emboli, miliary infarcts, miliary abscesses and especially, hemorrhagic infarcts may be found. Colonies of micro-organisms abound in the lumens of the smaller blood vessels. Streptococci are most frequently found but staphylococci are not rare. In the course of infections of intestinal origin, the colon bacillus is the most common cause. After birth, the pathogens are more varied depending on the environment.

Finally there are pulmonary lesions which result from the swallowing of particles of food. The infant vomits regurgitates, and allows the alimentary liquids to enter the bronchi. This causes a form of chemical softening of the lungs. The lung tissues are pale grey or brownish black with an acid gastric odor. These infants usually have severe dyspnea and high temperatures, and die within a period of 24 hours.

The avoidance of these pulmonary complications depends in part on better obstetrics, as the great majority are the result of long and difficult labors. The second factor is clearing of the bronchi, and too much importance cannot be attached to this factor. The catheter should be carried as far as possible in the airway. The usual methods of resuscitation should be used. Penicillin therapy or sulfanilamides are beneficial in the presence of infection.

CHARLES W. MUCKLE, M.D.

Studies in Erythroblastosis Fetalis. Activation of the Incomplete Rh Antibody by the Blood Serum of Full Term and Premature Newborn Infants. ERNEST WIKERSKY, MITCHELL I. ROBIN, and LILIAN M. YOUNG. *J Lab Clin M* 947 33-350

The failure to demonstrate Rh antibodies in the majority of sera obtained from mothers who have given birth to erythroblastic children was in a large part explained by the discovery of a second type of antibody variously called the "incomplete antibody" or "blocking antibody." This new type of antibody has been shown to agglutinate Rh positive cells provided that albumin solution or undiluted sera replaces saline solution as the diluent. The authors' experiments deal with the characteristics of sera in prenatal and postnatal life with regard to its capacity to actuate the incomplete Rh antibody.

Anti-Rh sera containing incomplete antibodies of low or average titer were activated by normal adult sera, but only slightly or not at all by normal cord sera. In contrast, other Rh sera such as those supposedly produced by immunization of volunteers and

containing incomplete antibodies of fairly high titer were activated by both normal adult sera and normal cord sera. However, even in the latter instances the average normal cord sera proved to be of somewhat weaker potency than the average normal adult sera.

Cord sera of premature babies are characterized by a definite weakness in activating potency which depends upon the age of the babies. The activating power of sera therefore depends upon a maturation principle which is subject to considerable individual variation. Experiments are described to demonstrate that the maturation of the activating capacity may continue after birth.

It seems reasonable that a relationship exists between the capacity of the baby's serum to activate the incomplete antibody and the clinical picture of erythroblastosis. The development of this maturation factor might explain the fact that clinical manifestations become evident only during the second part of pregnancy. The rapid increase in activating potency after birth may explain why some babies are born apparently normal and develop clinical manifestations after birth.

The question of treating erythroblastic babies with transfusions of adult blood deserves critical thought. Even though it is not possible as yet to prove an increase of activating potency in the baby's blood plasma following the injection of whole blood, the conclusion that adult plasma given to erythroblastic babies might possibly increase the danger of intravascular agglutination and hemolysis seems inescapable.

GEORGE BLUMBERG, M.D.

Studies in Erythroblastosis Fetalis. Investigations on the Detection of Sensitization of the Red Blood Cells of Newborn Infants with Erythroblastosis Fetalis. ERNEST WIKERSKY, MITCHELL I. ROBIN, LILLIAN M. YOUNGER, and LILIAN BLUM. *J Lab Clin M* 1047 33-1339.

The presence of free circulating Rh antibodies in the umbilical cord serum of an erythroblastic baby is a good indication that the baby has been sensitized. However many erythroblastic babies show either no such antibodies or only antibodies of low titer. In the absence of demonstrable Rh antibodies in the cord serum, the laboratory evidence of the baby's sensitization rests upon the demonstration of sensitization of his red blood cells.

A simple technique for the demonstration of sensitization of the red blood cells in an erythroblastic baby is described. Agglutination occurs when the packed blood cells of an erythroblastic baby are suspended in normal adult serum. This test can be carried out either in test tubes or on microscopic slides, the use of the latter proving more sensitive. The results obtained from this test indicate that the baby's cells are sensitized by the incomplete type of Rh antibody which does not cause agglutination in saline solution, and only slight agglutination, if any in cord serum.

In an experiment it was found that the addition of increasing amounts of adult serum to cord serum re-

sults in mixtures which have an increasing capacity to agglutinate the sensitized cells of a baby as measured by the technique described. However in contrast to these experimental results, blood samples obtained at regular intervals during an exchange transfusion failed to produce any visible agglutination of the baby's cells.

Some practical aspects concerning the validity and specificity of Rh type and blood group determination of erythroblastotic babies as well as the treatment of these babies by blood transfusion, are discussed.

GEORGE BLINCK, M.D.

Diarrhea of the Newborn. STEWART H. CLIFFORD
England J M 1947 237 969.

The author believes there has been a great increase in hospital deliveries in the past 10 years. Statistics from the Boston Lying In Hospital for the period from 1935 to 1945 show a decrease in home deliveries to almost zero about the same number of ward deliveries and a marked increase in private deliveries.

An all time low maternal mortality apparently justifies the public's belief that the maternity hospital is the safest place to have a baby but the author believes it must be proved whether or not it is the safest place for the newborn.

The literature on epidemic diarrhea has appeared only during the past 25 years and coincides with the shifting of deliveries from the home to the hospital.

Many factors have contributed to the increased hazard to the newborn infant in the hospitals. Increased birth rate and increased numbers of hospital deliveries have led to serious overcrowding in nurseries. Shortage of personnel has led to breakdowns in nursery and formula room technique. Adequate space is often not provided for nurseries and the space provided is often left over space wholly inadequate for the number of bassinets required.

The syndrome described as epidemic diarrhea of the newborn is not one pathologic entity but a miscellaneous group of cases of various etiologies known and unknown bound together by the common symptom of diarrhea. The reported epidemics can be divided into three groups. The first group shows evidence of bacterial origin the infecting agent enters the nursery via an adult carrier and reaches the infant by the fecal-oral route through a break in nursery or formula room technique. Several reports of epidemics are reviewed showing several organisms as the causative agents. In most of the epidemics there were epidemics of diarrhea in the local population contaminated milk supplies, or the mothers or nurses had either diarrhea or the organisms cultured from them were common to the infants affected.

Newborn infants are very susceptible to these infections and are extremely vulnerable because the attendants who feed them and handle the bottles and nipples also handle the excreta. Many epidemics can be traced to nursery personnel through faulty technique.

The second group includes those in which a virus is the agent or is strongly suspected. Several epidemics

were reviewed. In some of these there were also local outbreaks of so-called "gastric influenza" in the community. In some of these cases the stools were filtered and passed through young calves who also developed the disease. In some epidemics no specific agent was found although the infants had low white cell counts and did not respond to chemotherapy. The lack of a relatively simple technique to identify the virus of the disease is the greatest handicap to further progress. The method of growing the virus in newborn calves is of limited usefulness.

The third group includes those cases in which no virus can be identified and none of the bacterial pathogens are found. This group constitutes by far the largest one reported by the public press and public health officials. Several epidemics are reviewed and in them gross breaks in nursing technique are uncovered.

The prevention of epidemic diarrhea depends on strict nursery and formula room technique and the co-operation of epidemiologic and bacteriologic experts.

There are published standards of practice which if followed by all nurseries would go a long way toward removing the hazard of epidemic diarrhea in the newborn. It is disastrous to temporize with these diseases.

MISCELLANEOUS

Considerations on Obesity and the Gravidopuerperal State (Consideraciones sobre obesidad y estado puerperal) AMARCO STANLEY. Obis gin lai Amer., 1947 3 393.

The marked proportion of parturient women in Uruguay weighing more than 100 kgs. is explained by a diet rich in starches, sugars and fats coupled with the tendency to a sedentary existence. The author justifies the fact that his arguments are based upon clinical impressions rather than upon statistics based on the material under his personal observation by stating that he does not trust these figures too much since they arise from a very special clientele. However he agrees with Professor Tureme who in his article on the subject of the "distocia anular" (Anales de la Universidad Montevideo 1930 38) emphasized the importance of the consideration of adiposity which arises from endogenous causes tends as a rule to sterility however females with the exogenous variety of obesity do not seem to be relatively less fertile than the corresponding females of normal body weight.

The diagnosis of pregnancy in enormously obese women is not only difficult in the majority of cases but is at times practically impossible requiring in the first half of pregnancy every assistance at the disposal of the medical laboratory and in the second half of pregnancy rendering indispensable the aid of roentgenology. Especially difficult in these cases may be the detection of the presence of multiple pregnancy.

Adding their quota to the uncertainties of obstetrical management are (1) the tendency to gigantism in the fetus (especially in the cases of hyperglycemia or actual diabetes) and (2) the effects of the laws of Duncan, Hecker and Wernich postulating an increased fetal size and weight with the advancing age of the mother and with each succeeding pregnancy. Especially deceiving is the history of perfectly eutocic previous deliveries when the patient was not so obese. In many of these patients a perfectly physiological childbirth is encountered however when dystocia does arise it creates a serious obstetrical problem. Not only is the occurrence of the difficulty almost unpredictable, but when it does arise it is apt to demand special skill and knowledge on the part of the medical attendant. The usual disturbance in the progress of the labor is one of engagement and descent. Later the problem of the so-called "shoulder dystocia" (gigantic fetus) may arise. Of course cases have been reported in which the masses of fatty tissue in the pouch of Douglas would seem to have acted as a forelying obstruction to the descent of the presenting part, and the engagement is frequently delayed by the weakness of the fat-infiltrated uterine musculature however the delay in progress of the fetus into the pelvis is also frequently the result of tonic uterine contraction demanding relaxant measures rather than oxytocics. This contracted state of the uterus (annular dystocia) has frequently been mistaken for uterine inertia.

The author believes that every pregnant woman weighing more than 100 kgs. should be hospitalized and subjected to special study. Failure to recognize the necessity for intervention in time, in dystocia is a sin of omission but there is also the possibility of the other extreme the organic laxity of the obese person must always be kept in mind and the hazards of surgical intervention should be given earnest consideration.

JOHN W. BRECKMAN, M.D.

Obstetrical Accidents of Electrocoagulation of the Cervix (Les accidents obstétricaux de l'électrocoagulation du col utérin) HENRI VERMELIN. *Rev. f. gyn. obst.*, 1947, 4, 61.

The author analyzed the effects of electrocoagulation of the cervix in a series of 26 patients. Six pa-

tients were pregnant when electrocoagulation was practiced, and 3 of them aborted. Twenty patients were electrocoagulated before their pregnancy commenced.

Of the 21 patients who carried their pregnancies to term, 6 were delivered without difficulty. Nine patients had labors lasting more than 24 hours and digital dilatation was necessary 15 times. In 2 cases digital and instrumental dilatation was unsuccessful. In 3 cases total occlusion of the cervix required cesarean section, in 1 case followed by hysterectomy. Five patients had febrile postpartum periods. Two infants died in the course of delivery.

In patients with simple agglutination of the external orifice digital examination showed a slight depression, and boring at this point with the finger resulted in easy dilatation.

In other patients dilatation proceeded to approximately 5 cm. and examination revealed a poorly effaced cervix which was of the consistency of boiled leather which dilated with the greatest difficulty if at all.

In some patients no dilatation or effacement could be perceived, and the cervix was found to be transformed into a solid undilatable block of tissue.

The cause of these dystocias depends on several factors: defective coagulation, absence of care following coagulation, and the condition of the tissues coagulated.

The object of electrocoagulation was to destroy the mucosa. This was less dangerous when superficial coagulation was performed under good visualization. The skill and experience of the operator were very important when intracervical coagulation was performed, and it must be remembered that repeated superficial coagulations at low intensity may be equally as severe as a single coagulation at high intensity.

Following electrocoagulation it was very necessary to be certain that the external os was soft and pliable and if necessary to dilate the cervix to avoid stenosis.

All cervical tissue does not offer the same resistance, and the effects of coagulation may also vary with the hydration and vascularity of the tissues.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Pheochromocytoma J W S BLACKLOCK J W FERGUSON W S BLACK J SHAFAR and T SYMON-TON. *Brit J Surg* 1947 35 179.

The clinical diagnosis of pheochromocytoma is usually made on the basis of attacks of paroxysmal hypertension. This tumor gives rise to a syndrome that would appear to depend upon the discharge of adrenalin or adrenalinlike substances into the blood stream. Six cases of pheochromocytoma along with numerous microscopic photographs are presented in detail in this article. The authors' cases fall into four fairly well defined clinical groups.

Group 1. The adrenergic sympathetic syndrome illustrated by cases 1 and 2. The symptoms in this group are explained by excessive and intermittent excretion of adrenalin into the blood stream. In cases 1 and 2 it was shown histologically that abundant pro-adrenalin granules were present in the cells of the growth and these granules were observed to pass from the tumor cells into the capillaries. The tumors in both cases were of moderate size, one weighing 86 gm and the other 70 gm, whereas those in the asymptomatic group were very much smaller. The cardiovascular disturbances were most striking. The systolic pressure was raised (160 mm in case 1 and over 300 mm in case 2), the diastolic pressure was correspondingly elevated. There was marked and widespread vasoconstriction, the pulse often being thin and sometimes impalpable. Symptoms referable to the cardiovascular system are sometimes observed including palpitations, precordial pain, pain of an anginal nature, and a feeling of constriction around the chest. Electrocardiographic changes are frequently reported but these show no consistent or distinct pattern. A sinking feeling in the abdomen, numbness in the extremities, choking sensations, dizziness, feelings of anxiety, paresthesias, sensations of heat around the face and sweating have been described in published reports. Headaches are frequent and may be of a "pounding" character. Nausea and vomiting, especially if the seizure succeeds a meal, are frequently reported but diarrhea is less common. During an attack the urinary output may fall and albumin, red blood cells, and casts have occasionally been found. The blood sugar tends to rise with the rise in the blood pressure, thus elevated blood sugar levels and glycosuria are common. There is a wide range in the duration of the paroxysms, for they may last a few minutes or as long as 36 hours. Following the attack, a feeling of weakness and prostration is commonly experienced, especially if the attack has been of long duration. The fall in blood pressure is usually rapid and it sometimes reaches subnormal levels. Between the attacks the patient usually feels well, the blood pressure readings are normal as a rule, but the tendency for persistent

hypertension to develop increases with the duration of the disease.

Group 2. Persistent hypertension. This group may show the clinical features of either benign or malignant hypertension. Cardiac, renal and cerebral manifestations may appear and short of finding a local mass in the region of the adrenal glands there is no distinctive feature that can differentiate this group of cases from those of essential hypertension. In case 3 the tumor was small and no radiological examination would have established the diagnosis clinically. Because the clinical picture of essential hypertension and chronic nephritis may simulate that of pheochromocytoma, the cases of this group may be misdiagnosed.

Group 3. Asymptomatic. This group is usually found at postmortem examination. In cases 4 and 5 of the authors' series there was no indication either from the history or the clinical findings, that the patient had a pheochromocytoma.

Group 4. Malignant. The sixth case reported in this series was an example of a malignant tumor. After the removal of a well encapsulated tumor, there was extension of the process and at the time of death the entire left side of the abdomen and the medial portion of the hypochondrium was filled with tumor tissue.

Pyelography, either ascending or intravenous, may be helpful in establishing the diagnosis in this type of case.

A large tumor will cause a considerable displacement downward of the kidney on the involved side, but even a minor degree of renal ptosis may be significant, especially when it is suspected from the clinical evidence that an adrenal tumor is present. When dealing with smaller tumors or hyperplasia of the adrenal cortex, perrenal insufflation of air has proved to be of great value. A further clarification of the radiological picture can sometimes be achieved by taking intravenous pyelograms about two days after perrenal insufflation.

The preoperative treatment is important. The patient should be kept as quiet as possible before operation and heavy preoperative sedation should be given. The patient suffering from adrenal medullary tumors may be treated on a basis similar to that of patients with toxic goiters. They should be unaware of the time of their operation; otherwise, they are liable to develop a hypertensive attack immediately before it.

The authors made use of a renal extraperitoneal exposure in two of their cases, but they had to resect the last rib in both cases to improve the exposure of the upper part of the tumor.

Manipulation of a pheochromocytoma may cause a sharp rise in the blood pressure, which should be avoided as far as possible. By manipulation of the tumor during operation, large amounts of adrenalin

could quickly be liberated into the blood stream, causing shock thus, before handling the growth it is wise to ligate all vessels coming from the tumor to prevent as much as possible the entrance of adrenalin from the tumor into the general circulation. The upper pole of the kidney can be used as a retractor by pulling the kidney downward and slightly backward which brings the adrenal gland more into view.

As the cortex of the adrenal gland may be involved there may be interference with the secretion of cortical hormone. The therapeutic administration of cortical hormone therefore, should be carried out before and after operation.

Whether to give adrenalin postoperatively is a controversial point. It would appear from histological evidence that the patient is well supplied with adrenalin and further therapeutic administration of adrenalin may intensify the shock due to operation. Sudden withdrawal, however, of large amounts of adrenalin (from the tumor) to which the patient's tissues have been accustomed may cause collapse due to acute adrenalin insufficiency. The authors favor the postoperative medication suggested by Thorn *et al* who used adrenalin, cortical extract, blood transfusion and intravenous glucose saline postoperatively. CONRAD A. KUTNER, M.D.

Renal Salvage. AUSTIN I. DONSON, *J Urol* Balt., 947 52 993.

The author pleads for intelligent conservatism in renal surgery and laments the fact that renal surgery draws heavily upon the skill and knowledge of the surgeon and therefore is often not practiced to the patient's advantage. It is pointed out through clinical illustration that the renal mass which cannot support life is often detrimental both psychologically and physiologically when retained. It is with this in mind that the author carefully distinguishes intelligent conservatism from the mechanical application of a series of plastic renal procedures.

It is noted that one-third of all the nephrectomies done in the city of Richmond, Virginia, from 1930 to 1940 were done because of nephrolithiasis. It follows then that since bilateral nephrolithiasis occurs in from 10 to 20 per cent of all cases this pathological condition can be as dangerous as neoplasm and its surgical therapy must be planned with consideration.

There are reported 5 illustrative cases: 2 of nephrolithiasis and 3 of nephropoikils with pyelectasis. All of the patients were treated surgically without nephrectomy but with excellent results in all except 1 patient who presented a nonfunctioning kidney, with stone, on one side, and a poorly functioning kidney with stone on the opposite side. Stones were removed from both kidneys and a persistent sinus from the nonfunctioning kidney necessitated a secondary nephrectomy with resultant essentially normal urine.

Three instances of nephropoikils with bilateral hydronephrosis were discussed. Conservative renal surgery was exercised with the employment of plastic procedures of the renal pelvis and reimplanta-

tion of the ureter when indicated. Every attempt to preserve renal tissue in these patients was made because of the dictum of Hinman that the ability of renal repair is encouraged by the insufficiency of the opposite kidney and the fact that complete renal destruction occurs more frequently in unilateral hydronephrosis. In this regard the findings of Deming are presented. Deming found that in 37 of 60 patients with unilateral hydronephrosis there was total renal destruction as compared to 3 in 16 patients with bilateral hydronephrosis. The need for conservatism in renal surgery is emphasized by the detailed presentation of the several cases mentioned.

ROBERT LICH, JR., M.D.

Hemangioma of the Kidney. JOHN B. LOWMYER, SAMUEL BARON and HAROLD LEPIERUZE, *J Urol* Balt., 1947 58, 417.

The pathological findings in 2 cases of hemangioma of the kidney as well as the significant findings are reported by the authors. The chief symptom presented by the 2 patients was lumbar pain usually associated with gross hematuria without other urinary symptoms. It was significant that the roentgenological evidence was equivocal. Exploration of the renal area with subsequent nephrectomy was necessitated after the authors failed to establish a diagnosis definitely.

The pathological examination in the authors' first case revealed honeycombing of a small area near the renal pelvis. Microscopic section of the honeycombed area showed a cavernous hemangioma which impinged on the pelvis with a small channel into the pelvis. In the authors' second case the pelvis and a calyx at the upper pole were slightly dilated. A rounded blood cyst projected into the dilated calyx, which on section seemed to communicate with a large blood channel. This appeared to be an aneurysmal dilatation arising from a large vessel. Around the large vessels were clusters of small vessels. Microscopically the tumor consisted of large irregular blood spaces separated by fibrous tissue. Herniating into the blood spaces was a thick walled artery which appeared to have communicated with the large blood space, but an actual site of rupture could not be demonstrated.

These 2 cases are added to the total of 48 already found in the literature. The authors suggest that hemangioma of the kidney be considered in the differential diagnosis of those cases which satisfy the criteria initially enumerated.

PETER L. SCARDINO, M.D.

The Significance of Hematuria in Renal Tuberculosis. (Une signification de l'hématurie dans la tuberculose rénale.) RICH KUTNER, *J urol. med. Pat.*, 945-947 53 997.

In studying the insidious and localized form of renal tuberculosis—the type of kidney tuberculosis that is most liable to escape nephrectomy—the author was struck with the frequency with which the disease was associated with hematuria. Hematuria has a prog-

nostic value in kidney tuberculosis and the author tries to evaluate its precise significance in the disease.

The present study is based on 74 cases of hematuria in renal tuberculosis from the Urological Clinic of Dr Cochlin the observations of Professor Cibert, and on various published reports from the French Urological Society.

Of 74 patients with hemorrhagic tuberculosis, 52 were nephrectomized and the following anatomical findings were observed:

In 7 cases the primary lesions occurred in the cortical and medullary portion without communication with the urinary tract. The lesions consisted of tuberculous granulations or a sclerotic type of tissue. In 17 cases the lesions were ulcerated or caseous communicating with the calices, and consisted of ulcerations involving one or two of the pyramids. In many patients the isolated cavities were the size of a pea, a bean, a cherry or a nut, some were smooth walled or with sinus formation. In 6 cases the lesions were closed and contained clear or mastic fluid. Six of the kidneys were reduced to pyonephrosis.

In the first three classes of cases the association of renal pain and hematuria with ejaculation of blood on cystoscopic examination proved that the source of the bleeding was the kidney. The disappearance of bleeding following nephrectomy confirmed the fact that the original source of the hematuria was the involved kidney. On the contrary, in the patients with pyonephrosis the persistence of the hematuria following nephrectomy led the author to believe that the remaining kidney was the original source of the hematuria.

In 37 of 46 patients (after those with pyonephrosis had been eliminated) examination proved that the lesions were small, limited to one or two small portions of the kidney and that the rest of the kidney was normal.

The results of this anatomical study confirm the belief that bleeding was always from small or minimal lesions of renal tuberculosis. The author concludes that the hematuria was not indicative of the earliest lesion of tuberculosis but rather that it suggested a phase, the initial state of the disease.

A case reported by Vincenti who discovered two granulations in the cortex after hematuria of 8 years duration, is cited. Another case is cited in which a minimal lesion of renal tuberculosis was discovered after years of intermittent hematuria. The author believed it was logical to state that hematuria was a sign of a particular advancement of the lesion different from that usually observed. He did not believe that alarming hematuria always means an extension of the process, for it may remain almost identical on intravenous pyelography after successive episodes of hematuria. The rarity of hematuria in caseous and fibrous forms of the disease can be explained by a study of the anatomicopathological lesion. The vessels showed progressive thrombosis with obliteration of the vascular lumen, the lymphocytic infiltration along with the giant cells being responsible for the vascular lesion. This is the reason that it was

often said that hematuria in renal tuberculosis diminishes in frequency as the disease progresses. In the slowly progressive and hidden lesions the process of fibrosis provided a defense for the surrounding tissue, and also a protective role for the vessels.

Several more cases were cited by the author to emphasize the long interval of hematuria without apparent progression of the disease.

The author found 12 cases of cystitis in the series not including 4 cases of cystitis associated with hydronephrosis; the percentage was very much lower than that reported by Marlon and Cibert.

The lesions were inoperable in 22 of the cases observed. 8 of these were bilateral. In 17 cases the lesions increased in size after a period of 5 years in 7 cases after 10 years and in 5 cases after 8 years.

The absence of extension of the process to the bladder and the long course of the disease with the possibility of healing were considered by Kues to be clinically characteristic of the disease. It was considered possible that a number of hematurias were diagnosed as nephritis, hemorrhagic pyelonephritis or cryptogenic hematurias rather than renal tuberculosis.

Reference is made to a case of hematuria due to renal tuberculosis in which the diagnosis was made in 1941 after episodes of hematuria in 1928, 1931 and 1937. At a time when advocates of early cystomictic nephrectomy are convinced that it is impossible to foresee the evolution of renal tuberculosis, and a second group are advocating nephrectomy based upon the progressive characteristics of the disease, the significance of hematuria warrants a place in the discussion of therapeutic indications.

In resume, the author believes that hematuria can at times be interpreted as an indication of a healing process, and that the cicatrization tendency, the absence of cystitis and the prolonged course of the disease, with a healing tendency favors expectant treatment rather than early nephrectomy.

CONRAD A. KUEHN, M.D.

Papillomatous Disease of the Renal Pelvis. J. B. MACALPINE. *Brit. J. Surg.*, 1947, 35, 113.

The author presented an analysis of 19 cases of papillomatous tumor of the renal pelvis, encountered personally in the span of 29 years and followed up for a long period.

A papilloma may be benign in one part and malignant in another. The tumor may be benign in its early stages and become malignant later. Secondary deposits do not necessarily resemble the primary focus. Whenever papillomatous material is implanted in a wound, whether the neoplasm in the original situation be benign or malignant, the implant will behave as a malignant one. A transference from a primary focus in the bladder or ureter to the pelvis does not occur as an implant but is always transferred with the stream of the urine. A possible exception may take place in hydronephrosis, in which an implant falls into a dilated calyx and takes root.

There appears to be a definite relationship between stone formation and the growth of the renal pelvis.

About 50 per cent of all squamous tumors of the pelvis occur in association with stone. The transitional epithelium of the pelvis in some cases becomes leucoplakic.

A definite diagnosis of this lesion is made either when tumor cells are found in the urine (the bladder being free from disease) or when a papilloma protrudes from the urethral orifice as noted cystoscopically. Pyelograms may show a characteristic filling defect, but often they show the secondary effects, such as pyelectasis.

The correct treatment is ureteronephrectomy. The ureter must be cut flush with the bladder; there is no need for removal of the urethral segment of the bladder. Seedlings within the intramural ureter must be destroyed.

ROBERT TURELL, M.D.

Papillomas of the Renal Pelvis in Dye Workers. J. B. MACALPINE. *Brit. J. Surg.* 1947 35: 137

Since the work of Rehn published in 1895, it has been known that papillomatous disease of the urinary bladder is more prevalent among dye workers than among members of the general population. The author has seen many such vesical neoplasms among dye workers in Manchester, England.

In the present communication the author reports a series of papillomas of the renal pelvis. In one of the patients, who had had antecedent vesical papillomas, the lesion occurred bilaterally. In one patient the renal tumor was discovered 4 years after discovery of the vesical neoplasm, and in the other patient, 5 years after discovery of the vesical neoplasm.

The author states that in one case the tumor was overlooked until it had grown to a large size in spite of periodic cystoscopic examinations. Because of this error it later became routine practice to perform excretory urography at relatively short intervals in these papilloma-forming individuals. A perusal of the literature disclosed reports of 6 other cases of papillomatous disease in the upper urinary tract of dye workers.

ROBERT TURELL, M.D.

Wilms' Tumor. GERRY L. FERRIS, SHERIDAN H. SAEVER, CHARLES E. PAMORY and MICHAEL JACOB. *J. Urol.* Balt., 1947 58: 397

The authors have added 3 cases to the previously 54 reported cases of Wilms' tumor occurring in adults. They give detailed descriptions of the clinical laboratory and pathological findings in the 3 cases.

The occurrence of Wilms' tumor adenomyosarcoma, is apparently not rare in the adult. It has been postulated that when the tumor fails to manifest itself in childhood it is probably the result of arrested development of a myotome which embryologically became included in the development of the kidney. When the tumors fail to develop until adult life, 80 per cent manifest themselves in the fourth, fifth and sixth decades.

The preoperative diagnosis of Wilms' tumor frequently presents a difficult problem. The so-called

diagnostic triad hematuria, pain, and abdominal mass, was infrequently of diagnostic assistance. In the 3 cases reported by the authors the common findings were an unusually large kidney mass associated with a high elevation in temperature but unaccompanied by any noticeable urinary infection. The prognosis is more unfavorable than the known poor prognosis in children.

The diagnosis never having been made preoperatively in an adult, there is no record of preoperative x-ray therapy. Surgery supplemented in an occasional case by deep x-ray therapy has usually been the treatment of choice.

PETER L. SCARDINO, M.D.

Wilms' Tumor. C. M. BURROKS. *J. Urol.* Balt., 1947 58: 418.

Wilms' tumor is a highly malignant neoplasm occurring most frequently prior to the third year but about once in 15,000 hospital admissions. The early diagnosis of this tumor remains somewhat difficult since it fails to give rise to noticeable symptoms in its early stages. The first sign in the child is usually abdominal swelling, but here again one must consider neuroblastoma, hypernephroma, free peritoneal embryoma, and hydronephrosis in the differential diagnosis. The surgeon frequently and perhaps fortunately must resort to exploration to establish the diagnosis. It is of great interest that certain operators have reduced the mortality from 98 per cent during the period from 1914 to 1933 to 40 per cent from 1934 to 1941 by removing the tumor as soon as the diagnosis has been made clinically without preoperative x-ray therapy. The larger tumors are taken out transabdominally. Postoperatively the patients receive x-ray therapy but not because of any known beneficial results. It is known, states the author, that irradiation has never destroyed a metastatic lesion.

The author reports a 3 year cure of a 3 year old female child whose diagnosis was facilitated by a "fortunate" minor accident resulting in pain in the left upper quadrant, vomiting, and a rigid tender abdomen with elevation of the temperature. These symptoms focused the attention of the author on a lesion in the left upper abdomen. The preoperative diagnosis was ruptured intraperitoneal viscus. An emergency exploratory laparotomy was performed with a left subcostal incision. A large retroperitoneal mass was observed but the operator elected not to attempt removal of the mass at this time. Eleven days later utilizing the transperitoneal approach of Ladd, the tumor was removed. Gross inspection revealed that the tumor was small, occupying the lower pole of the kidney. The remainder of the mass was the enlarged kidney due to intracapsular hemorrhage. Microscopically the tumor was a typical Wilms' tumor. Adjacent lymph nodes failed to show tumor microscopically. Postoperatively a full course of deep x-ray therapy was administered beginning a week after discharge. Check-ups at 6 month intervals have failed to reveal metastases. The author is

perhaps justifiably optimistic since it has been authoritatively reported that no patient surviving 2 years has died later of the original Wilms tumor

PETER L. SCARDINO, M.D.

Retropertoneal Tumors of Gerota's Perirenal Adipose Space (Tumor retroperitoneal de la at mosiera adiposa pararenal de Gerota) A. GRANARA COSTA. *Rev argent urol* 1946 15 301

Retropertoneal tumors in the strict sense of the word may be divided according to their location into median lateral or lumbosacral and those of the lesser pelvic cavity. The tumors may be cystic or solid. Approximately 50 per cent of the tumors are malignant. The following are encountered in descending order of frequency: lipomas, fibrolipomas, fibromas, fibromyomas, and myxomas.

The majority of authors when referring to lumbar retroperitoneal tumors have in mind those closely connected with the kidneys and located within Zuckerkandl's fascia. However tumors may develop in Gerota's pararenal fatty tissue.

Retropertoneal tumors are, as a rule, multilobular and have an elastic consistency and a grayish color. Moderate pain and a sensation of heaviness are usually the first symptoms.

Inspection may detect a tumefaction of the involved region when the tumor has attained a certain size. A collateral venous network and less frequently a varicocele may be found. The tumor does not move with respiration. On percussion a zone of dullness may be found in places not covered by the large intestines while a characteristic sonorous sound may be produced in front and below the tumor. Roentgenograms reveal a shadow which may be confluent with that of the liver. The hepatic or splenic flexure is pushed toward the median line and downward. Intravenous pyelography shows that the tumor is adjacent to the kidney but does not involve it. Retrograde pyelography reveals similar conditions. Functional tests of the kidneys show the organs to be normal. Edema of the lower extremities or ascites is rare. If the tumor is benign it is usually of slow evolution.

The differential diagnosis of a tumor of Gerota's space should include kidney tumors, those of the perirenal space or the liver and cysts of the pancreas, mesentery and ovaries. Roentgenograms taken in the lateral direction are very valuable because they may show a shadow between the spine and the kidney. The latter may be displaced toward the midline. The tumor is always situated behind and below the kidney. Perirenal and pararenal tumors usually can be differentiated only at operation.

The treatment is surgical. The twelfth rib may have to be resected. A vertical incision from the axilla to the iliac bone offers good exposure. Large tumors require the transperitoneal approach.

The author removed a tumor of Gerota's space from a man 38 years of age. The weight of the tumor was 1.3 kgm. The histologic diagnosis was fibromyxosarcoma.

JOSEPH K. NARAT, M.D.

Tuberculosis of the Terminal Portion of the Ureter (La tubercolosi del tratto terminale dell uretere) ANTONIO MANFREDI. *Rass internaz dis. inf.* 1947 37 333

The histologic findings in a large number of cases show that tuberculous infection of the ureter occurs essentially by two different routes: the canalicular and the adventitial.

Early localization of the specific infection at the vesical end of the ureter, owing to the fact that this portion is the lowest point at which the urine is normally stopped for a moment before it passes into the bladder, is revealed by careful observation of serial sections. The resultant spasmodic state of the ureteral extremity, although incapable of causing a real and persistent retention, nevertheless produces an overfilling of the canal with urine and interferes with the normal peristaltic waves. The more prolonged contact of the infected urine with the ureteral mucosa and the contemporaneous circulatory disturbances facilitate a slow and uniform ascending dissemination of the bacilli over the entire length of the canal without causing a simultaneous dilatation like that which is observed in chronic ureteropyelitis secondary to retention of urine in the bladder. At the same time the specific infection also invades the ureteral adventitia essentially by the lymphatic route and proceeds downward from the cellular tissue of the renal hilus along the connective tissue strata which surround the ureter. The severity of this infection, therefore, decreases gradually toward the lower end of the ureter. The superimposition of the two processes, which by two different routes (internal canalicular and external adventitial) advance in opposite directions, results in the classical macroscopic aspect of tuberculous ureteritis under the form of a thick, rather hard cylinder, more or less regular in its entire length with restricted lumen or completely abolished lumen.

The author does not deny that other processes may establish the specific infection of the ureter as he realizes there are no organic barriers capable of offering permanent and insurmountable resistance to the tubercle bacillus.

RICHARD KIMMEL, M.D.

Cystectomy and Ureteral Transplantation DAVID A. DREILING and A. HYMAN. *J Urol* Balt. 1947 58 435

The authors report the case of a patient who, at 47 years, was found to have an infiltrating papillomatous vesical tumor involving the left posterior wall and the dome to the right of the midline. Biopsy showed an infiltrating medullary carcinoma with involvement of the lymphatics. A hysterogram demonstrated submucous fibroids and the uterus was found to be slightly enlarged with an irregular surface due to the presence of small myomas. The cervix revealed leucoplakia and severe erosion. The blood was not significantly abnormal and the urine showed many red blood cells.

At exploratory laparotomy the bladder was found to be the seat of an extensive infiltrating tumor in

two distinct masses, and on the anterior surface of the uterus there was a nodule which suggested a carcinomatous implant. There was no distinct involvement of the lymph nodes, nor distant metastases. Immediate resection of the bladder and uterus was indicated and a preliminary ureteroenterostomy was believed to be ill advised because of the imminent threat of neoplastic spread. At the conclusion of the uterine and vesical resection the patient's condition would not permit a ureteroenterostomy and a bilateral ureterocutaneous implantation was accomplished. A histological study of the surgical specimens showed no neoplastic process in the uterus and the vesical lesion had as yet not penetrated the serosa.

Following surgery the ureters retracted from the skin edges and there developed finally a ureterocutaneous vaginal fistula. After a period of drainage of urine from the operative wound and final closure of the retracted initial ureterocutaneous openings, the patient's suprapubic wound closed and the urine drained only through the vagina.

Eighteen weeks following the first operation the patient was again operated upon in the attempt to complete a right ureteroenteric anastomosis. Four weeks later the left ureter was implanted into the bowel. The course following these procedures was benign and the patient was discharged from the hospital.

Five months later the patient was readmitted for biopsy of a mass in the right groin. The biopsy specimen demonstrated adenocarcinoma and the patient died 3 months later or 13 months following the initial surgery.

At autopsy there was found widely disseminated carcinomatous and the urinary tract demonstrated chronic pyelonephritis. It is interesting that the right ureteroenterostomy opening was plugged at least partially by a retained portion of the rubber tube used when the Coffey III operation was performed. The authors consider this a rare but significant complication.

The case reported illustrates quite vividly the fact that ureterocutaneous implantation does not contraindicate future ureteroenterostomy even in the face of serious local complications since even in this instance the cause of death was carcinomatous rather than renal failure due to an unsuccessful implantation.

ROBERT LICH, JR., M.D.

BLADDER, URETHRA, AND PENIS

Vesical Diverticula. HARRY M. SPENCE and SYDNEY S. BAIRD, *J. Urol. Balt.*, 1947, 58, 337

A series of 35 cases of vesical diverticula is analyzed and the principles underlying their clinical management are reviewed. The cases are divided into 3 groups: (1) cases in which no treatment or palliative treatment only was administered; (2) those in which transurethral resection only was performed; and (3) those in which diverticulectomy with surgery of the bladder neck, as indicated, was carried out.

The etiology of vesical diverticula consists of some interference with bladder emptying which results in an outpouching of the mucosa through points of congenital weakness of the bladder musculature. This results in accumulations devoid of muscle fibers, and hence lacking in expulsive power. The size of the orifice may vary from that of a pin point to a diameter of a centimeter or so.

Diverticula are more common in men of middle age or beyond but they occur also in women and occasionally in younger individuals.

The causative obstructive factor in the authors' series was adenomatous hyperplasia of the prostate in 16 patients, median bar or fibrous contracture of the bladder neck in 7, urethral stricture in 6, neurogenic dysfunction in 2, and urethral valves in 2 patients. In 3 cases no cause was demonstrable.

There are no pathognomonic symptoms of vesical diverticulum. The symptoms of bladder neck obstruction plus those of infection which is usually present, constitute the clinical picture. Residual urine, often of a foul character, is a prominent feature. Gross hematuria may occur.

Certain complicating lesions may occur in conjunction with diverticula, such as carcinoma arising in or involving a diverticulum, and calculi in the diverticulum or lying in the bladder in the form of a "dumb-bell" stone. Occasionally the ureteral orifice opens into the diverticulum and complicates the operation.

The treatment of vesical diverticula consists of correction of the bladder neck obstruction and elimination of the retention and concomitant sepsis in the diverticulum proper. In the small, wide-mouthed freely emptying sac, relief of bladder neck obstruction alone may suffice. In the larger types diverticulectomy is necessary sooner or later to restore normal micturition.

The authors believe that diverticulectomy should be performed as a primary procedure whenever retention in the diverticulum is demonstrated irrespective of the size of the sac. To perform a transurethral resection of the prostate initially and watch the outcome of this on the emptying of the diverticulum, results too often in an unduly prolonged convalescence and an unsatisfactory end result.

The authors recommend the technique of diverticulectomy described by Barnes and by Pearson which consists of the removal of the mucosal lining from within the fibrous sac. Once the line of cleavage is established this procedure is carried out with great ease and avoidance of injury to adjacent structures. After opening and exploring the bladder the index finger is inserted through the orifice of the diverticulum and the neck of the latter is severed extravesically. Through an incision in the upper lateral aspect of the diverticulum the plane of cleavage is found and the mucosal lining is removed. The hole in the bladder is then closed from within the denuded diverticulum sac, which is drained and left *in situ*. Cigarette drains are used freely and left in place for at least 1 week. The bladder may be closed about a

suprapubic tube (Pearson) or closed tightly a urethral catheter being used for drainage (Barnes)
FREDERICK A. LLOYD, M.D.

Intraperitoneal Rupture of Bladder CHARLES
DOROVAN TOOL, *J. Urol.*, Balt., 1947 53 431

The author reviews the literature with reference to the infrequency of intraperitoneal rupture of the urinary bladder in the female. Its rarity is emphasized. Reports were found of only 5 cases and of this group 2 patients did not have an associated fracture of the bony pelvis. The apparent reason for the infrequent occurrence of intraperitoneal rupture of the bladder in the female is that the bladder is distinctly an intrapelvic organ unless it is greatly filled with urine or is displaced into the abdomen by a gravid uterus. In the child and in the male, the bladder occupies more of an abdominal position and is covered by peritoneum over a larger surface. Hence intraperitoneal vesical rupture is potentially greater.

The case is reported of a 15 year old girl who was injured in an automobile accident. She was found to have an intraperitoneal rupture of the urinary bladder associated with a greatly displaced pelvic fracture. Due to associated injuries the patient died before any surgical treatment could be under taken.

ROBERT LICE, JR., M.D.

Deslating Gangrene of the Bladder (Gangrena disecante de vejiga) RODOLFO GONZALEZ, *Rev. argent. med.* 1946, 15 171

Gonzalez reports the case of a 50 year old woman who apparently was recovering from the gripe when symptoms referable to her bladder occurred. The condition progressed rapidly. Hematuria and pyuria, as well as vesical tenesmus became severe. A purulent urethral mass appeared which made catheterization imperative. There was a foul urinary odor and the patient's condition showed a general toxic infection. Pneumonia set in and the patient expired. Autopsy revealed gangrene of the bladder with total necrosis of the mucosa, submucosa, and internal muscular coat.

Theories regarding the cause and pathogenesis point to (1) toxicologic factors such as incarceration of the bladder by a gravid uterus and compression by instruments (2) infections such as typhoid fever, meningitis, and gripe (3) physicochemical factors such as instilled hot or caustic solutions, x ray burns, radium, and (4) nerve factors.

The symptomatology and prognosis of the disease are discussed. Drainage is essential in the treatment in order to permit extraction and expulsion of the mucosa and prevent retrograde spread to the kidney.

STEPHEN A. ZIEGLER, M.D.

Disembrioplastic Tumor of the Bladder; Chondrosarcoma (Tumor disembrioplastico de vejiga condrosarcoma) LEON D. AARUZ and ARTURO DI PIETRO, *Rev. argent. med.* 1946 15 137

This is a case report of a 60 year old male who complained of ardor, dysuria, and hematuria for 3

months. Cystoscopic examination revealed a bladder tumor which was removed by radioblasty.

Pathologic studies revealed a tumor with predominant round cell infiltration, some differentiated in aliform cells, and a zone of adult cartilage associated with undifferentiated and embryonal elements. This led to the interpretation that the tumor arose from a mesenchymal embryonic rest.

This type of tumor is rare and two theories are proposed with regard to its origin. One states that the tumor is a metaplasia of the vesical mucosa, whereas the other states that it is an inclusion of a wolffian rest obtained during the formation of the trigone. It has several names: fusiform cellular sarcoma, rhabdomyosarcoma, and leiomyosarcoma.

STEPHEN A. ZIEGLER, M.D.

The Treatment of Bladder Cancer RALPH SHACK
MAN, *Brit. J. Surg.* 1947 35 140

The first instance of cancer of the urinary bladder was recorded in 1593. Operations for bladder neoplasms have been performed since the early part of the seventeenth century. Albarran having ascribed the first recorded operation to Covillard. In 1874 Billroth performed a suprapubic resection of a bladder tumor. Sonnenburg in 1885 performed a partial cystectomy with excision of the local peritoneum. In 1887 Nitze introduced the cystoscope and subsequently elaborated the method of transurethral cystoscopic removal of the tumor with the aid of a snare, followed by cauterization of the raw base. In 1910 Edwin Beer of New York introduced the high frequency current for transurethral diathermy. Barringer in 1922 and Hugh Young in 1923 introduced the therapeutic application of radium.

Total cystectomy was first carried out in 1887 but in 1915 French surgeons advocated this as the method of choice for the treatment of vesical cancer. The first successful transplantation of ureters to the bowel was performed in 1852 but it was not until 1931 when Coffey reported his series of transplantations of the ureters in 35 patients that the method began to gain popularity.

Between the years from 1935 to 1946 the author observed 76 cases of carcinoma of the bladder. Thirty of these patients were considered suitable for radical treatment which consisted of partial or complete cystectomy after ureterocolic anastomosis.

Ureteric transplantation and complete cystectomy was contemplated in 21 patients. Of these 12 died (a mortality of 57 per cent) at some stage of the operative program.

Partial cystectomy which can only be performed if the neoplasm is situated in a favorable site, was performed nine times with no mortality but with a recurrence in 5 patients.

Cutaneous ureterostomy was performed in one patient who died 4 days after operation of peritonitis and uremia.

The late results of treatment were poor and quite similar to those of treatment of gastric cancer.

ROBERT TURELL, M.D.

Urethral Diverticulum. W. GRAHAM KNOX. *J Urol* Balt., 1947 58: 344.

The occurrence of congenital diverticulum of the urethra in the male is rare. In the majority of cases reported in the literature, urethral diverticulum in the male is of the so-called acquired type. These diverticula are most often located in the posterior urethra for here is where the more complex structures of the prostatic portion give rise to a great variety of pathologic processes capable of acting as precursors of a diverticulum. Among these are included the gonococcal infections and complications, straddle injuries, strictures, instrumentation accidents and the lodgment of calculi, either vesical or prostatic in origin. The congenital lesions are confined for the most part to the anterior or pendulous urethra. They occur in the midline and usually arise from the floor of the urethra.

Congenital cysts arising from glandular rests may rupture into the urethra, thus forming diverticula.

Congenital diverticula may be asymptomatic for many years, and their presence may then be discovered because of secondary inflammatory changes resulting from urinary stasis in their lumen. A few have been discovered by chance during endoscopic and x ray examination for an unrelated complaint. Symptoms vary from minimal incontinence to a most distressing frequency and tenesmus, the latter more marked when the lesion is near the sphincter.

Occasionally the diagnosis is difficult to make. It is simplified by the presence of a palpable swelling on the ventral penile shaft but as is usually the case, the external genitalia show no abnormality and the patient is suspected of having merely a urethritis. He is often treated for such, and the opening of the diverticulum which may be quite small, is missed during endoscopy. The diagnosis is made most readily by careful study of a cystourethrogram. The bladder is filled with 200 c.c. of 50 per cent skiodan and views are taken during or right after the patient has been allowed to urinate approximately one-half the amount of the dye.

If allowed to go untreated, congenital diverticula are likely to become the source of an inflammatory process which potentially may lead to suppuration anywhere in the urinary tract. Occasionally calculus formation or fistulous tracts have been reported as arising in them. Since palliative measures such as urethral dilatation, chemotherapy or endoscopic enlargement of the neck of the diverticulum have not proved satisfactory. It would appear that surgical excision of the sac is the procedure of choice. Excellent exposure is obtained with the patient in the lithotomy position and the use of a vertical midline incision. This should be placed posterior to the scrotum to avoid a fistula. Careful plastic repair of the urethra over a fairly large rubber catheter will prevent stricture postoperatively. The complication of wound infection leading to fistula must be considered and adherence to rigid aseptic technique, accurate hemostasis and careful approximation of the wound layers should be stressed.

The author reports the case of a congenital diverticulum of the urethra in an 18 year old male who complained of incontinence of from 10 to 15 c.c. of urine, 15 to 20 minutes after micturition for 3 months prior to admission. Anteroposterior and lateral urethrograms revealed dilatation, to 3 times normal size, of the proximal third of the pendulous urethra.

An attempt was made to plicate the bulbocavernosus muscle over the corpus cavernosum urethrae in the hope that this would permit voluntary emptying of the sac or its obliteration by external pressure, but this was of no avail and 1 month later the diverticulum was resected. An uneventful recovery followed.

FREDERICK A. LYON, M.D.

GENITAL ORGANS

Heterotopic Bone Formation after Prostatectomy
B. S. AXENBOOM. *J Urol* Balt., 1948 59: 50.

Extraskeletal heterotopic bone formation may be classified as of the periosteal, fascial, muscular or combined type. It is a rare lesion and the incidence is greater following intraperitoneal operations than suprapubic operations on the bladder and prostate. This is explained by some writers as being due to the fact that the linea transversa of the rectus muscle is the embryological remnant of a rib and that the linea alba is the downward proliferation of the sternum. A total of 17 cases of heterotopic bone formation following suprapubic operation have been reported previously and the author's case brings this total to 18. A number of theories have been advanced as to the pathogenesis and etiology of this lesion, but none has received widespread support. Trauma seems definitely to be a predisposing factor. It is to be emphasized that this lesion is composed of true cancellous bone in the majority of cases, and is not simply calcification of a soft tissue.

Careful palpation establishes the diagnosis, which must be differentiated from the following conditions: foreign body, osteitis pubis, hematoma of muscle, tumor (either of soft tissue or bone), leiomyosarcoma, faulty healing following fracture of the pubic bone, congenital osteoma of the skin and calcification or ossification in a malignant tumor in the suprapubic area. The treatment is excision of the growth.

Abeabou reports the case of a 54 year old Jewish male who underwent a two stage suprapubic prostatectomy and cystolithotomy, and a subsequent excision of fibrous tissue with a Young's prostatic punch. Convalescence was uneventful, but 6 weeks after operation a 4 cm. knoblike mass was palpated in the upper end of the incision. Roentgenograms supported the diagnosis of heterotopic bone formation. Excision was carried out and the bone was found to be attached to the lower layer of the rectus sheath and extended into the body of the rectus muscle. Microscopic study disclosed the presence of fully developed bony trabeculae within which there were Haversian canal systems. The patient was followed up for 3 years and showed no signs of recurrence.

JOSEPH E. MAURER, M.D.

The Importance of Brucellosis Orchiepididymitis
(Orchiepididymitis brucellosa, su importancia) GUN-
LEO JACAPRERO *Rev argent urol.*, 1940 15 39.

Brucellosis as cause of orchitis and epididymitis has received little attention and practically never enters into the differential diagnosis of urinary or genital lesions. However in the author's country the disease is frequent enough that it must always be ruled out whenever genital tuberculosis postgonorrheal or pyogenic lesions are encountered. This should be the case whenever pasteurization of milk is not done.

Because of the variable symptomatology of brucellosis, clinical diagnosis for the most part must depend upon laboratory findings. The cardinal symptoms are fever, sweats, pains or aches, asthenia, splenomegaly and constipation while the accessory symptoms include anemia, hepatomegaly, orchiditis, epididymitis and adenitis. The various clinical forms of the disease are hemorrhagic pulmonary, pseudotuberculous, hepatic, nervous and urogenital. The last named is by no means an exceptional or rare complication. According to the author genital complications ranged between 4 and 40 per cent, 13 occurring during the febrile period and 3 during convalescence. There were 10 patients with epididymitis, 3 with prostatovesiculitis, 2 with urethritis, 1 with vasculitis and 1 with vasculitis and funiculitis.

STEPHEN A. ZIMAN, M.D.

Perineal Testicle. ARTHUR B. CECIL, J. *Lond. Med.* 1947 58, 384.

The author presents a very succinct account of ectopia of the testicle with a review of the theories of normal and abnormal testicular migration. The patient whose case is reported suffered an ectopic testicle of perineal location which is the one-hundred and fourth case reported in the literature.

The perineal testicle lies freely movable in the perineum on either side of the median raphe and between an imaginary line drawn behind the scrotum and in front of the anus. The scrotum of these patients is asymmetrical, containing both a normal and rudimentary pouch.

The case reported was that of a 25 year old individual who presented a congenitally misplaced perineal testicle. The testicle was approached through a left inguinal incision and the cord isolated. The testicle was then felt in the depths of the perineum, but could not be satisfactorily outlined. A perineal incision was made and after a rather firm gubernaculum was divided the testicle was delivered through the abdominal wound without difficulty. The rudimentary left portion of the scrotum was enlarged through the normal scrotal ring was absent. The testicle, which was found to have an adequate cord, was placed in the newly created scrotal pocket. A scrotal ring was formed and the wounds closed without attachment of the testicle to the scrotum. The resultant repair was entirely satisfactory.

ROBERT LUCE, JR., M.D.

Epididymotesticular Infarct or Apoplexy (Infarto o apopleja epididimotesticular) RODOLFO DE SERRA *CAHARD Rev. As med. argent.*, 1947 61 644.

Epididymotesticular apoplexy is a rare entity. Its etiology is not known, although its mechanism may be due to an arterial infarct, a thrombus, or a capillary apoplexy. The symptoms and diagnosis are so similar to torsion that the surgeon often resorts to expectant treatment with consequent ill results. An immediate castration as was done in the author's case may give more promising results, however they have not as yet been evaluated.

The testicle was 58 mm. in length and 38 mm. in its transverse diameter. The spermatic cord was swollen due to the edema of the connective tissue. The vas deferens appeared to be injected with blood. The microscopic examination showed that both the arterial and venous blood vessels were obliterated by thrombi while an inflammatory infiltration covered all of the vascular layers.

ARTHUR F. CIPOLLA, M.D.

Malignant Epithelial Tumors of the Testis (I tumori epiteliali maligni del testicolo) SALVATORE D'ARRIGO *Gior. med.*, Palermo 1947 4, 116.

The histogenesis of testicular tumors is uncertain. Therefore the classification of these tumors is based on their morphological aspects. Carcinomas of the testis which constitute the greater part of the testicular neoplasms may be divided into two groups, namely seminomas and polymorphous epitheliomas. This classification is justified because both groups have distinct histological aspects and differ from one another clinically and biologically. The term polymorphous epitheliomas comprises a variety of carcinomas such as those with glandular aspect, papilliferous formations, cystic glandular structure, syncytiomas and mesotheliomas. The cells may be cylindrical, cuboid or may resemble endothelium.

ARTHUR F. CIPOLLA, M.D.

MISCELLANEOUS

Excretory Urography by the Intramuscular Route in Admits (Urografia excretoria per la via intramuscolare en el adulto) RICARDO BERNARDI *Rev argent urol.*, 1940 15 379.

The author states that intramuscular urography offers advantages over the intravenous route in cases in which the veins are difficult to find in which repeated injections of hypertonic glucose solution occlude the blood vessels or the sclerosis of veins is caused by the treatment of renal insufficiency. The results compare favorably with those following intravenous injections of opaque medium.

To diminish pain novocain is added. The author mixes 20 c.c. of nitasol with 20 to 30 c.c. of a 1 per cent novocain and normal saline solution to make a total amount of 40 to 50 c.c. Twenty five cubic centimeters of the mixture are injected into the gluteal region and roentgenograms are taken 30, 60 and 90 minutes later. The needles should be

6 to 10 cm. long because shorter ones deposit the solution in the fat tissue instead of the muscles.

It should be remembered that absorption and excretion of the injected solution take place much faster in children than in adults.

The x-ray images are clearer in patients with one kidney whether this be a congenital or acquired condition. The same statement applies to patients with but one functioning kidney.

It is advisable to divide the total amount of solution into two equal parts, each to be injected into the right or left gluteal region, respectively. Occasionally a sensitivity at the site of the injection may remain for 1 or 2 days. The pain may be relieved by warm applications.

JOSEPH K. NARAT, M.D.

High Resection of the Vas Deferens in Genital Tuberculosis (*La deferentectomia alta en las tuberculosis genitales quirúrgicas*) GUILLERMO LACAPRERO *Rev. argent. urol.* 946 5 147

Total resection of the vas is recommended in the cure of tuberculous orchidoepididymitis, the scrotal as well as the inguinal portions should be excised even to the prostatic area, particularly when the lesion involves the internal inguinal region.

The development of the disease is so variable that there is no way to determine which course it may take. Involvement of the prostate and bladder is perhaps more frequent than that of the testicles when the vas contains the primary focus. Secondary spread is intercanalicular via the lymphatics or adjacent structures.

The results of high resection were uniformly good in the hands of the author although it was shown that urinary fistula may occur following high deferentectomy.

STEPHEN A. ZIEKAK, M.D.

Cancer of the Male Breast Secondary to Estrogenic Administration WILLIAM ARAMON and H. WARMAN *Wkly. J. Urol.*, Balt., 948, 59 76.

Lacassagne in 1933 made the first report of the development of breast cancer following the injection of estrogens in male mice of a strain in which the incidence of cancer was high in the female. From the practical standpoint it seems one must accept the conclusion that when there is no estrogenic stimulation there is no development of mammary tumors in male mice.

It is well known that diethylstilbestrol causes increase in thickness of the ducts of the breast tissue, along with increased vascularity and connective tissue proliferation.

Development of cancer of the breast following the use of stilbestrol therapy in the male has not been reported but 3 cases in the female have been reported.

The authors report the case of a 51 year old negro who had terminal metastatic carcinoma of the prostate and was treated with 5,007 mgm. of diethylstilbestrol over a period of 489 days. The breasts were normal at the beginning of treatment, but post mortem examination revealed irregular firm, nodular masses in both breasts. These were adherent to the pectoral fascia. Section revealed diffuse neoplastic, infiltrative growth with involvement of the axillary nodes. General metastases were present from the carcinoma of the prostate. Histopathological examination of the breast tissue showed diffuse, infiltrating growth with myxomatous stroma, and marked hyperplastic changes in the ductal epithelium. Pathological diagnosis was cancer of the breast, and carcinoma of the prostate.

JOSEPH E. MAURER, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES JOINTS MUSCLES TENDONS, ETC.

On Injuries of Bone and Bone Marrow after Intravenous Injections. LUNNART WALLÉN *Acta chir scand* 1947 96 152.

The intraosseous technique has in recent years been used for the therapeutic injection of fluids stimulants, and narcotics when the intravenous route was not readily available. During use of intrataneously injected contrast media for urography pain occurred unless the solution was diluted to be isotonic. This suggested the possibility of tissue damage from hypertonic solutions.

Data on bone complications following intraosseous injections are few. In a series of 750 intraosseous injections reported by Sondergaard (1946) 5 cases (0.67%) of osteomyelitis occurred. Of a group of 23 patients in whom 50 per cent glucose was injected 32 times, 3 patients developed osteomyelitis. The author describes and presents the roentgenograms of the tibia of a child in whom a bone marrow needle was left *in situ* for 5 days for frequent injections of sulfathiazole. Recovery from meningitis followed but a periosteal reaction and irregular density of the bone was still apparent one year later. The intense alkalinity (pH 10.8) of sulfathiazole is suggested as the causative factor of this response.

Care in placing the needle is necessary so that the epiphysis is spared any danger of trauma. The needle should lie free in the marrow cavity so that subperiosteal extravasations and penetration of the opposite cortex are avoided.

Animal investigations correlating the x ray and histological findings at frequent intervals after the injection of various substances emphasize the limited sphere of usefulness of the intraosseous technique. In addition to the requirements for intravenous fluids, intraosseous fluids must approximately conform to the osmotic and acid base conditions of the blood. Chemical toxicity of certain contrast media studied was suspected as a factor contributing to the bone and bone marrow defects observed. Prime among the complications was thrombosis of certain vessels vital to sections of bone. Experimentally some of the degenerative changes in bone and marrow seem to be reversible but others have led to permanent deformity in the affected bone. The use of the intraosseous route is therefore, not without danger and should be used only when venous puncture is impossible. FRANCES E. BRENNER, M.D.

The Neuroendocrine Syndromes in Recklinghausen's Disease (Les syndromes neuro-endocriniens d'ostéolyse diffuse) PIERRE LOMBARD *Rev orthop* Par., 1947 33 312.

The origin of the disturbances which manifest themselves clinically as a process of osteolysis must

be sought much higher in the central nervous system than is generally admitted. The ganglia in the hypothalamic region of the diencephalon send and receive nerve impulses upward through the thalamus to the region of the cerebral cortex and downward toward the hypophysis and the vegetative nervous system to the farthest reaches of the body. However it is to the hypothalamus itself that the attention is particularly drawn by the clinical manifestations accompanying the process of osteolysis. In Recklinghausen's disease itself the osteoporotic process may be accompanied by pain which is neither radicular nor neuritic in character. There is frequently a weakening and wasting of the muscles accompanied by a marked hypotonia and reduced excitability to the electric current but without the reaction of degeneration. These manifestations could conceivably be ascribed to peripheral influences such as disturbances in the metabolism of calcium and phosphorus. However this cannot be affirmed for the cardiovascular signs such as tachycardia and sudden failure of the cardiac muscle, and the poliuria and renal pains resembling the crises of renal calculus.

The occasional attacks of tetany in this condition also point directly to the hypothalamus. The hypothalamus acts directly on the parathyroids by nerve impulses or through the hypophysis (the correlation between the hypophysis and hypothalamus is recognized) and results in the development of an adenoma in one of these glands. Indeed the fact that the adenoma develops in only one of these glands as a rule speaks against a local cause. In tetany the excitability of the facial nerve (Chovatek's sign) and the mental manifestations of irritability and eventually psychoses and mental confusion states speak for involvement at a high level of the brain. This tetany does not necessarily clear up with return of the calcium and phosphorus of the blood to normal. A similar type of tetany is frequently seen in conditions which are admittedly bound up with disturbances of the central nervous system (hypophysis-hypothalamic) such as those following certain thyroidectomies and puerperal eclampsia. In fact the manifestations in tetany are so poorly understood from the content of calcium and phosphorus in the blood that the author has been impelled to incriminate a toxic action of guanidine.

With regard to the general subject of osteomalacia—which becomes an extremely vague one when Recklinghausen's and Paget's diseases are excluded—this does not seem to be one condition etiologically considered but a number of osteomalacias such as those associated with pregnancy when the burden is imposed on the hypophysis and in turn on the hypothalamus, by the developing fetus and the subsequent lactation. Likewise the healing of this condition is brought about by oophorectomy which

can be compared to parathyroidectomy with regard to its effect on the neurovegetative system.

Likewise, there does not appear to be only one rachitis rather there are a number of rachitic conditions, of which the florid form encountered by the pediatrician approaches the adiposogenital syndrome of Froehlich, while the hypotrophic form of rachitis inclines toward Simmonds disease both are known to be of central origin.

The hypothalamohypophyseal origin of a diffuse osteolytic process is seen under a different aspect, but with greatest clarity in Albright's disease. Here the accompanying arrest of bodily growth, the premature closure of the epiphyses, the precocious puberty and the retardation of intellectual development is purely central. Also the patches of abnormal pigmentation are understood when the role of the hypothalamus and the hypophysis in the origin and transport of melanocytes is remembered.

Paget's disease is very similar to that of Recklinghausen's disease in many respects so similar indeed, that in many cases the two cannot be distinguished by means of the microscope and one condition seems at times to develop into the other. Paget's disease is admitted to be on a hypothalamo-hypophyseal basis and assumption of the same origin for Recklinghausen's disease would explain the similarity.

Finally it is pointed out that the disturbances of capillary permeability controlled by the neuroendocrine influence of the higher centers on the reticulo-endothelial system in its regulation of the metabolic exchanges going on in the bone do not always result in simple lysis of bone there are also places where osteoplastic processes predominate and result in osteoid proliferation bordering on tumor genesis and here the influence of the neuroendocrine and nervous systems on the processes of cell division and nuclear multiplications, culminating in the production of parathyroid and hypophyseal adenomas and in the proliferation of fibroplastic areas within the bone itself is related to tumor formation in general.

In this necessarily sketchy discussion of a vast subject the author tries to emphasize the fact that the problem of osteolysis must be reoriented to include systematic studies of the anatomic and functional disturbances of the vegetative ganglia in the diencephalic region of the brain.

JOHN W. BROWN, M.D.

A Case of Disseminated Cystic Fibrous Osteitis (Polyostotic Fibrous Dysplasia)—Albright's Syndrome (Sobre um caso de osteíte fibrosa cística disseminada, displasia fibrosa polioestótica—síndrome d'Albright). A. B. OLIVEIRA CINTRA, HELIO LOURENÇO DE OLIVEIRA, EMILIO MATTAR, YERONICA RAFF and EWALDO MARIO RUSSO. *Arq. dis.*, 947 57

The subject of this study was a girl of 19 who, at the age of 6 and after a cold developed a swelling on the right side of the head including the eyeball. A roentgenogram revealed changes in the frontal bone. She was sent to Germany and during the sea voyage

had a limp of the left extremity. The first diagnosis was Schneller-Christian disease, which was treated by roentgen therapy to the head and the left arm and thigh, in addition to oral and parenteral administration of calcium preparations. At the age of 11 she fell and fractured the upper third of her left arm and femur; at the age of 13½ she sustained another fracture of the upper third of the left femur. Later she had an exploration of the parathyroids because she was suspected of having Recklinghausen's disease but no abnormalities were discovered. Homeopathic treatment was instituted without success, as she had 7 incomplete fractures due to minimal causes during that time. After the age of 16 she felt stronger and by the age of 19 was leading a normal life, but she had a more fracture of the left wrist and arm. Menstruation started at the age of 13 and was normal.

Examination disclosed a prominence of the right frontal bone and supraorbital arch which displaced the eyeball downward outward and forward. Extension of the elbow was limited to about 60 degrees. The left lower extremity was shortened and a bony swelling was felt in the upper third of the left femur. The skin was normal. Roentgen examination revealed extensive lesions of fibrocystic osteodystrophy.

Of the 3 clinical entities which are capable of producing fibrocystic osteodystrophy (hyperparathyroidism, prolonged renal insufficiency and disseminated fibrous osteodystrophy) the third fits the present case. The first two entities were undoubtedly absent. Extensive and disseminated lesions were found in the bones in addition to perfectly normal bony structures. The preservation of the hard laminae of the teeth showed that there was no disease of a general demineralizing character. There were no alterations of the mineral metabolism caused by general disease. True enough there was an increase of phosphatase, but in view of the fact that any bone destruction followed by repair is characterized by increase of phosphatase this finding was of no special significance. There was also a slight decrease of the blood phosphorus which is encountered in hyperparathyroidism, but this isolated finding was of no diagnostic value and has been mentioned in some cases of well established Albright's syndrome. The blood calcium was normal and the urinary calcium was lowered to 53 mgm. per 24 hours, while in hyperparathyroidism calculuria is of fundamental importance for the diagnosis.

Consequently the present case shows a picture which corresponds to the polyostotic fibrous dysplasia of Lichtenstein and Jaffe and to the osseous component of Albright's syndrome in which the other characteristic changes are absent.

RICHARD KIDWELL, M.D.

Osteoid Osteoma. Review of the Literature and Report of 20 Cases. MARY S. SHERMAN. *J. Bone Surg.* 1947 29: 918.

Probably the first description of the pathological picture of osteoid osteoma was made by Bergstrand

who in 1930 reported 2 cases. In 1934 Milch described this lesion. He concluded that he was dealing with a benign osteoblastic tumor forming osteoid tissue and recommended surgical excision. To Jaffe in 1935 is due the credit for establishing this lesion as a distinct entity.

The etiology of these lesions is a subject of much debate. Trauma and infection have been considered etiological factors, however only 3 of the 30 cases reviewed by the author presented a distinct history of trauma. In no case has evidence of either acute or chronic infection been found. Following operation all wounds healed by primary intention. The pathological findings were constant and the author agrees with Jaffe that osteoid osteoma is not of infectious origin, but is best interpreted as a benign tumor.

DANIEL H. LEVINTHAL, M.D.

Eosinophilic Granuloma of Bone (La granulome eosinophile des os) LUCIEN LÉGER, R. DUCROQUET, P. GAUTHIER VILLARS, and S. TCHERKOFF *Presse Méd.* 1948 No 57 648.

A 2 year old boy had tenderness to pressure and spontaneous pain of the left thigh. Roentgen examination disclosed in the upper half of the femur a curious doubly contoured cyst measuring 8 by 3 cm. The cyst was surrounded by a thickened bony cortex. The focus was opened and curetted and a tibial implant was inserted. The symptoms were relieved at once, the cavity in the bone tended to fill in and assumed a polycystic appearance. However 6 months later the pain and limp recurred and the roentgenogram revealed that the tibial graft had been resorbed, the cavity had assumed a multicystic form and had broken through the cortex on the inner surface of the bone. Roentgen therapy was instituted in the dosage of 150 roentgens per session with 3 sessions per week. The total dosage was 3,000 roentgens. The multicystic lesion seemed to be healing at the time of this report and all symptoms had disappeared.

The blood picture was not characteristic and the blood smear exhibited merely an excess of lymphocytes. Histologic examination of the curettings disclosed two cell types. Irregular patches of small deeply staining cells characteristic of young connective tissue were dispersed in a matrix of reticular hyperplasia with large pale cells anastomosing with one another by means of long protoplasmic extensions. The nuclei of these reticular cells were central in location voluminous globular and sometimes doubled and there were frequent mitotic figures. Scattered about the microscopic field were small collections of leucocytes containing numerous eosinophils. The staining qualities and distribution of the tissue components seemed incompatible with a diagnosis of tumor. Foam cells were not identified.

Otani and Ehrlich (*Am J Path.* 1940 16 470) were the first to identify this condition histologically. The authors concede the probability expressed by Jaffe and Lichtenstein (*Am J Path.* 1940 16 595) that eosinophilic granuloma or histiocytic granuloma

as it is sometimes designated in South America, is etiologically related to the Schaller-Christian disease. The condition seems to run a definite course and heal in a few months whether it is treated or not, nevertheless the difficulty in distinguishing it from other conditions, such as tumors, and particularly from Recklinghausen's disease, osseous cysts, the reticuloses of the xanthomatous type, and reticulohistiomonocytosis, renders osseous biopsy imperative.

JOHN W. BRENNAN, M.D.

Madelung's Disease or Hemistrophy of the Internal Part of the Lower Radial Epiphysis (Doença de Madelung, hemistrofia epifisária interna radial inferior) HAROLDO ROSTA PORTELA. *Rev. Brasil Cir.* 1947 16 515.

This case is reported because of the rarity of the lesion and the excellent result obtained by surgical treatment.

Some years ago a girl who is now 16 had experienced pain in the wrists as if they were sprained and had worn leather wristbands until the condition improved. Her attention was then called to the fact that the bone had increased in size. She continued to have slight pain occasionally, which became worse when her wrists were used a great deal. Examination of the wrists disclosed on the posterior aspect of the cubital side a round swelling 2 cm. wide and 1 cm. high. Flexion and extension of the wrists did not change their anterior aspect. All active and passive movements were painful. Seen from the cubital side the wrists presented the aspect of the back of a fork, seen from the radial side there was an anterior curvature of the radius.

Palpation revealed a hard, painless swelling of the ulna which ended in an elevation corresponding to the styloid apophysis. Movements of flexion and extension showed that there was no articular connection between the lower end of the ulna and the carpal bones. The relationship between the radius and the carpal bones appeared to be normal. The two styloid apophyses were on the same level. Roentgen examination showed subluxation of the ulna with external and upward deviation and hemiatrophy of the internal part of the lower radial epiphysis with ascent of the first row of carpal bones, especially the semilunar. The diagnosis was Madelung's disease.

The left wrist was operated upon. A posterolateral incision of 10 cm. was made over the lower third of the forearm down to the bone. The soft tissues were retracted and a cuneiform osteotomy was done on the external aspect of the radius at the level of the epiphysis. The upper and lower portions of the radius were perforated and then approximated with kangaroo tendon. A posterointernal incision was made over the lower third of the ulna and 1.5 cm. of the diaphysis were resected. The upper and lower fragments were perforated and approximated with kangaroo tendon. The ulnar luxation was reduced, the wounds were closed with No. 1 catgut and a right angle plaster cast was applied. Recovery

as uneventful and, one year later the wrist was in excellent condition and all movements were normal.

RICHARD KIECKER, M.D.

Kienboeck Disease—Softening of the Semilunar Bone Following Slow Healing of the Wrist in Industrial Accidents (La enfermedad de Kienboeck—malacia del semilunar—como secuela tardía del cuerpo en los accidentados del trabajo. FRANCISCO FERNÁNDEZ ROSAS. *Prensa méd. argent.* 947 34-9 4

Decalcification with softening and fracture of the wrist bone of the laborer occurs more frequently than is supposed. It is the direct result of numerous minor injuries to the carpal area during work, due to twistings, pullings, contusions, or to associated lesions and fractures in the wrist. The condition at first may escape roentgen detection, but soon pain and muscle spasm set in and progress to the stage where the patient is incapacitated and unable to work. Limitation of active and passive motion is present in addition to swelling and edema of the lower third of the forearm. The disease is important as the articular dynamics of the wrist are disturbed. This leads to serious economic loss and cuts down the laborer's efficiency. Loss of function may run as high as 35 per cent and interposes a delicate medicolegal problem.

Excursion of the lunate bone, molding of the bone or periarterial sympathectomy of the humeral artery is recommended when the recognition of the disease is made early.

The case histories of 8 patients are appended and the medicolegal consideration of each is discussed. The paper is generously illustrated with roentgenograms of each case. STEPHEN A. ZIEGLER, M.D.

Medicolegal Considerations following Injuries of the Wrist (Consideraciones medicolegales de las secuelas de los traumatismos carpicos). FRANCISCO FERNÁNDEZ ROSAS. *Prensa méd. argent.*, 947 34-13 3.

This article considers affections which follow injuries to the wrist and the medicolegal questions which may arise when alterations in the hand or the articular dynamics of that member occur. Some of the pertinent conditions are (1) osteoporosis—Sudeck's syndrome (2) Koehler Monchet disease—scapho id softening (3) Kienboeck's disease—semilunar softening (4) pseudarthrosis of the scapho id and (5) arthritis arthrosis, or post traumatic osteoarthrosis.

These conditions are readily differentiated by anatomic, clinical and roentgenographic studies, but this becomes particularly difficult when the origin of the incapacitating complications is viewed before the law.

Factors to be considered when the injuries are reviewed for medicolegal opinion are classified as anatomic, functional, economic, the bone lesion itself, pain, alteration of the soft tissues, muscular power, articular movements, the economic value of the

hand, and the cause-and-effect relationship to the accident. The capacity must be appraised in percentage values—as 30 per cent disability or 70 per cent usefulness.

Case studies of 9 examples are given.

STEPHEN A. ZIEGLER, M.D.

Backward Displacement of Fifth Lumbar Vertebra in Degenerative Disc Disease. The Significance of the Difference in Anteroposterior Diameters of the Fifth Lumbar and First Sacral Vertebrae. GILBERT H. FLETCHER. *J. Bone Surg.* 1947 39 019.

In the present study based upon 600 roentgenograms of the spine, the author demonstrates that posterior displacement of the fifth lumbar on the first sacral vertebra is a definite pathological occurrence. It is not a separate entity but is a mechanical consequence of degenerative disc disease. The difference in size of the fifth lumbar and first sacral vertebrae has an etiological significance in the production of these degenerative changes.

The universal symptom was backache, most often in the low back limitation of motion and sciatica were commonly associated complaints. All of the roentgenograms were taken with the patient in the recumbent position.

In about 10 per cent of the group or 56 spines, there was posterior displacement (at least 4 millimeters) of the posteroinferior border of the fifth lumbar vertebra in relation to the posterosuperior border of the first sacral vertebra.

From the data presented, the following facts can be stated concerning backward displacement of the fifth lumbar vertebra on the first sacral vertebra:

1. From roentgenograms, the author has confirmed the observation made by Willis from measurements of skeletons, namely that there is often a difference in the diameters of the fifth lumbar and first sacral vertebrae. This difference existed in 87 per cent of the cases with backward displacement, and in practically none of the control group.

2. This difference in diameters was found to account for only about one-half of the apparent backward displacement in 85 per cent of the cases in this series, thus disproving the suggestion that such displacement is only an optical illusion.

3. Backward displacement is usually associated with degenerative changes in the posterior fibers of the annulus fibrosus and a high incidence of advanced degenerative disc disease.

4. From the facts stated in No. 1 and No. 3 above, one sees a correlation between differences in diameters and disc disease.

5. There is no exaggeration of the lumbosacral angle in backward displacement.

6. The lower lumbar and the upper sacral facets are of frontal, or predominantly frontal, type and are in a plane directed downward and backward.

The cause of backward displacement lies in the narrowing of the disc and the amount of displacement will depend upon the obliquity of the facets.

It has been shown that both a high incidence of degenerative changes in the lumbosacral disc and a shortened first sacral vertebra are found in the group with backward displacement while outside of this group there was no difference in size of the fifth lumbar and first sacral vertebrae, and a very low incidence of disc disease, which leads to the inference that there is a correlation between a shortened first sacral vertebra and degenerative changes in the lumbosacral disc.

When such a difference in size exists, the posterior border of the fifth lumbar vertebra overhangs that of the first sacral vertebra so that the posterior fibers of the annulus fibrosus are oblique instead of vertical. This creates an abnormal strain on these fibers and accelerates the processes of byalinization and fissuring which take place during life. This fissuring opens avenues to leakage and dehydration of the nucleus pulposus. The narrowing of the posterior margin results from the degenerative changes in the annulus fibrosus and is followed by thinning of the whole disc.

The differentiation of disc herniation from degenerative disc disease is obviously of great therapeutic importance because in disc disease there is no heretofore material to remove for the purpose of alleviating pressure on the nerve roots. This explains in great part the poor results following surgery. Instead it would seem logical in the presence of disc disease and actual backward displacement to fuse the lumbosacral joint with the lumbosacral junction in hyperflexion in order to reduce the vertebral slipping as much as possible and to improve the width of the intervertebral foramina.

RUDOLPH S. REICH M.D.

Osteochondritis and Coxa Vara in Congenital Subluxation of the Hip, Cured by the Abduction Treatment (Osteochondritis e coxa vara in prelussazioni curate con l'abduzione) GIULIENNO DE LUCCI. *Chir. org. medim.*, 1947 31 193

Hilgenreiner in 1938 again called attention to the fact that in the treatment of subluxation of the hip by abduction osteochondritic changes of the femoral epiphysis developed quite frequently. He was of the opinion that these changes might be due to the method of treatment.

In a statistical study of 777 patients treated at the Istituto Ortopedico Rizzoli, Scaglietti found that 2.18 per cent of the patients treated by the abduction method later developed evidence of osteochondritis of the femoral head.

Selected cases are presented with excellent x-ray films from the collection of the Istituto Rizzoli. It is the author's opinion from this study that osteochondritis of the hip and the coxa vara which develops during the treatment by abduction or years later is not the result of the type of treatment but the result of the primary dysplasia of the bone which is due to altered osteogenesis. This conclusion was first brought forth in 1915 by Delitala. He clearly stated that one cannot consider coxa plana and congenital

dislocation of the hip as parts of the same disease in one there is alteration of form and in the other an alteration in the osteogenesis of the bone.

CARLO SCUDERI M.D.

Large Pseudocyst of the Tibia; the Result of a Chronic Staphylococcus Osteoperiostitis. (Voluminosa pseudocisti ossea della tibia da osteoperiostiti cronica stafilococcica) R. FIORELLINO. *Ann. Ital. Chir.*, 1947 24 303

The author describes a case of large pseudocyst of the tibia which falls into the category first described by Poncet in 1874. This type of infection has a particular predilection for the periosteum which is in juxtaposition to the epiphysis of the long bones. This disease is occasionally seen in children and adolescents, but rarely in adults.

The cavity of the bone is filled with a semigelatinous material which has a very high albumin content.

The author's case was that of a 14-year-old boy who had a large pseudocystic mass in the middle third of the tibia. This mass was the result of a chronic osteitis and periostitis due to the *Staphylococcus aureus*. The patient made an uneventful recovery following incision, evacuation of the cystic mass, partial collapse of the cavity and primary closure of the wound.

A discussion of the various forms of chronic bone infection is presented in the article.

CARLO SCUDERI M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES TENDONS ETC.

The Treatment of Chronic Osteomyelitis by the Use of Spongy Bone Grafting (O tratamento da osteomielite crônica pelo emprego de enxerto de osso esponjoso) FLAVIO PIRES DE CAMARCO. *Rev. Hosp. Clin.*, 1947 2 227

All efforts must be made to achieve rapid and sound healing of chronic osteomyelitis in order to avoid its complications and sequelae. Because of the modern bacteriostatic drugs it is possible to excise thoroughly all fibrous and infected tissues and to follow this by early surgical repair practically without danger to life or limb. Cancellous bone from the ilium is the best material for filling dead spaces created by the intervention. The donor areas of the ilium where cancellous bone is most abundant are immediately below the anterosuperior iliac spine and at the level of the posterosuperior iliac spine.

An incision is made along the anterior border of the iliac crest beginning at the anterosuperior spine and extending for 5 or 6 cm. and the crest is exposed without damage to the muscular insertions. With chisel and mallet the upper part of the bone is raised but not completely detached. The internal and external cortical layers are detached to expose the mass of pure cancellous bone which is removed in small fragments. It is important not to include any cortical bone among the removed fragments because it would imperil the grafting and not to injure the in-

ternal cortex especially in the posterior donor area, because of the vicinity of the sacroiliac joint. When a sufficient amount of cancellous bone has been collected the two cortical layers are approximated, the iliac crest is returned to its original position, and careful suture of the wound is performed. More hematoma forms in the anterior donor area than in the posterior area, but drainage is not necessary a compressive dressing suffices.

The osteomyelitic focus is then carefully excised all eburnated and infected bone being removed the excision must also include the fibrosed and infected soft tissues so as to leave only tissues with adequate circulation in contact with the remaining bone. The defect in the bone is then completely filled with cancellous bone fragments and the wound is closed in one plane. A dry dressing and a plaster cast are applied.

As preoperative and postoperative care is of great importance for the success of the operation the patients were hospitalized 4 days before operation and were given 800,000 units of penicillin daily in addition to the treatment of their general condition. Penicillin was continued for 8 days after the operation.

Three cases are reported. In the first 2 patients, with hematogenous osteomyelitis of the femur and the tibia, the dressing was removed 30 days after operation. Healing was complete, with closure of all fistulas, and a roentgenogram showed perfect assimilation of the graft. The patients were walking casts for 30 days, and were examined 14 months after operation when they were found to be completely cured. In the third patient, with osteomyelitis following open fracture of the tibia, loss of soft tissues had left the bone exposed. Excision of the focus, cancellous bone grafting, and skin grafting were done in one operation and consolidation of the bone graft was complete in 3 months. The patient began to walk without apparatus a month later 11 months after operation he is walking well and has only slight limitation of the movements of the knee.

RICHARD KEMEL, M.D.

Primary Tendon Suture. MARK B. COVERTY and NORMAN E. BECK. *J. Am. M. Ass.* 1947 135 80.

In the period from January 1, 1935 to January 1, 1945, primary suture of the tendons of the hand and wrist was performed at the Mayo Clinic in 43 cases. Tendon lacerations, compound fractures, and avulsions are encountered fairly commonly in the same case at the clinic because of the accidents which occur in the large surrounding rural community.

Forty patients were traced and 28 of them had obtained excellent or good results. The poorest results were obtained when lacerations of the tendons of the flexor muscles occurred in the finger through the fibrous tendinous sheath. Careful adherence to the rules presented gives a higher percentage of good results. Two or more surgical procedures are necessary in many cases before all that can be done for the patient is accomplished.

The poor results have been evaluated carefully. In some cases they were due to infection. In others, to suture of the tendon of the flexor digitorum sublimis as well as the tendon of the flexor digitorum profundus, and in 1 case, to prolonged splinting. In some of the cases in which the result was classed as poor there seemed to be factors which were beyond control.

Arthrodesis of the Elbow. A Preliminary Report of a New Operation. MORRIS GRILMAN. *J. Bone Surg.* 1947 29: 850.

Indications for elbow fusion are relatively few although numerous techniques for the procedure have been described. The operation presented here is not too formidable and has several distinct advantages. Relatively uninvolved bone surfaces are brought into contact, and bone from the operative area is used for a graft which is easily anchored. The radiohumeral joint is preserved and the elbow may be fixed at any desired angle without further operative interference.

Through a medial approach the humerus and ulna adjacent to the joint are exposed anteriorly and the medial epicondyle is chiseled flush with the humeral shaft from above downward. A wire passed through the epicondyle into the humerus controls this wedge which is the graft. It is rotated down to lie on the anterior ulna, and is outlined on the ulnar surface. This wedge of the anterior ulnar cortex is now removed and the freshened humeral fragment fitted into the defect snugly. The angle of fixation is determined and wires or bone pegs through the ulna stabilize the graft in the desired position. The remaining bone chips may be packed in where needed.

The ulnar nerve is transposed anteriorly if it seems to be under tension. Soft tissue closure is made and a plaster shoulder spica cast is applied. When the cast is changed at 8 weeks the protruding wires are removed and the cast is replaced until firm fusion is secured.

One case of tuberculosis of the elbow in a 13 year old boy treated by this technique, is described. Fusion was present at 28 weeks.

FRANCIS E. BRIDGEMAN, M.D.

Transposition of Fingers in Severe Injuries of the Hand. WALTER C. GRAHAM, J. BARRETT BROWN, BRADFORD CAMRON, and DANIEL C. RICHARD. *J. Bone Surg.* 1947 29: 908.

Penetrating wounds of the hand caused by missiles may result in irreparable deformities with scar formation and nerve injuries which occasionally lead to the amputation of one or more fingers. Amputation of the thumb and index finger, two of the most important components of the hand, requires serious consideration regarding restoration of the sacrificed parts. Surgical rehabilitation of or substitution for either of these two digits should be encouraged. Reconstructive procedures of the hand must have two objectives attaining optimum function and achieving an excellent cosmetic result.

As long ago as 1921 Nuzzi Rinaldo and Tonnini performed the operative procedure which will be described. Since 1921 however only an occasional case treated in this manner has appeared in the literature.

The ring finger is substituted for by the fifth finger existing scar tissue with the involved metacarpal down to the base, to leave the blood and nerve supply intact. After osteotomizing the metacarpal of the ring finger the fifth digit is transposed on the fourth metacarpal. While this procedure narrows the hand it improves functional value and enhances the extirpation of the middle finger an osteotomy metacarpal is transposed upon the partially excised third metacarpal bone.

In the absence of a thumb the authors favor excision of the scar removal of the second metacarpal and excision of $\frac{3}{4}$ to 1 inch of the proximal phalanx of the index finger. It being freed from its bed and allowed to retract approximately 2 inches from its original length. The index finger is fixed upon the first metacarpal in moderate ulnar deviation. Immobilization is achieved by Kirschner wire thrust through three adjacent fingers. Occupational therapy is instituted after the healing phases.

SAMUEL L. GOVERNALL, M.D.

Facial Repair for Poliomyelitic Paralysis of the Abdominal Wall in Adults. GEORGE T. WALLACE and WILLIAM J. WEST *J Bone Surg* 1947 39 1031

The importance of abdominal wall defects as related to infantile paralysis was not recognized until Lowman brought the subject to our attention in 1932. Despite pioneer work in the use of fascial grafts the surgical procedure has not been accepted by all clinics as the method of treatment of severely paralyzed patients, possibly because of the surgeon's inability to recognize the advisability of the procedure, or the patient's unwillingness to be operated upon.

At the Army Poliomyelitis Center where only patients with severe paralysis are cared for the problem of rehabilitation has been of extreme concern. Of 66 patients with poliomyelitis, 74 per cent had some degree of abdominal paralysis.

The purpose of this paper is to report 12 abdominal fascial transplantations in 9 cases of residual abdominal paralysis and to show concretely the degree of improvement obtained in each case.

Suitable candidates for surgery preoperative care described in detail. Four patients had had sufficient abdominal paralysis to necessitate two surgical procedures, and 5 patients have needed one surgical procedure. A second operation is to be performed in another case. The second operation is usually performed 3 weeks following the first.

A chart has been devised to show the amount of improvement obtained based on the ability of the

individual to do things which had previously been impossible for him. None of the patients was impaired by the operative procedure. Improvement in balance has been constant in each case. The second physical function in which all patients have shown improvement is walking. A very important improvement observed in all of the patients has been the ability to get on and off a commode 5 patients now being able to accomplish this routine without assistance. Seven patients have noticed improvement in getting in and out of their braces.

These patients must learn to use their new abdominal support. They must learn how to bring the shoulders back and the thoracic cage up in order to put maximum tension on the transplanted fascia, and thus bring forward the anterior portion of the pelvis. This action transmits the needed power from the arms, shoulders, and chest to the lower leg through the fascial straps. It takes a considerable length of time to learn how to do this depending upon the amount of shoulder and chest involvement present.

It is the belief of the authors that if the patient has shown no improvement in the strength of the abdominal muscles for a period of 3 months reconstructive surgery of the type described is indicated. In their opinion a long period of convalescence (before considering surgery) causing atrophy of muscles which were not primarily involved hinders progress. It is an error to consider operation only if all other methods of treatment fail.

It has been noted that after the first few patients in the present series had been operated upon other patients became aware of the postoperative improvement and some have asked if they too might be candidates for a similar procedure.

RUDOLPH S. REICH, M.D.

Fusion of the Hip in Children. The Chandler Method CHARLES N. PEASE, *J Bone Surg* 1947 39 874.

The purpose of fusion of the hip is to replace the involved bone and soft tissue of the hip by a newly transplanted bone from the homolateral femur. The coalescence of the transplanted bone with its inevitable fibroblastic proliferation not only enhances healing but obliterates the pathologic process. Hence the removal of necrotic and tuberculous granulation tissue with subsequent substitution of healthy bone invariably produces a favorable site for new bone formation and connective tissue growth.

The author's study is comprised of 28 children in whom the Chandler operation was performed, and a complete 5 year follow up is presented. Twenty three fusions were done for tuberculosis of the hip 4 for subsiding pyogenic infection and 1 fusion was done for congenital dislocation of the hip. The average age of the children was 7 7 years. No deaths were recorded immediately following the surgery. However three patients died of tuberculous meningitis one year or more after the surgical intervention. The

latter patients suffered from simultaneous tuberculous lesions elsewhere.

The technique of the operation is as follows:

A lateral incision is made, extending from below the crest of the ilium to the junction of the upper and middle thirds of the thigh and splitting the tensor fasciae latae, the vastus lateralis, and the periosteum. The incision is further extended toward the femoral neck and traverses the upper acetabular margin and ilium above the latter.

A generous graft is osteotomized from the trochanter and includes from 3 to 5 inches of the femoral shaft. The graft is placed in Ringer's solution until ready to be used. All articular surfaces of the head of the femur and acetabulum are removed. A recess is made in the ilium for the implantation of the osteoperiosteal graft. Bone chips are obtained from the shaft of the femur to aid in the obliteration of the attenuated hip joint. After the graft has been properly driven under the outer ala of the ilium the incision is closed and a spica cast is applied.

In as much as failure of fusion and subsequent postoperative deformities have been attributable to the powerful adductor muscles of the thigh the author deems it advisable to perform an extraperitoneal section of the obturator nerve (Chandler). Flexion deformity and pseudarthrosis can also be eliminated by this procedure.

SAMUEL L. GOVERNALL, M.D.

Bridge Arthrodesis for Tuberculosis of the Pubis
(Artrodesi ponte per tuberculosi del pube) E.
MILITONE. *Chir. org. modern.* 1947 3 203.

Tuberculosis of the pubis is the rarest of joint tuberculosis. Only a few hundred cases have been reported.

A report of a case in a 38 year old housewife is reported. This patient was treated by the use of an osteoperiosteal transplant removed from the tibia and placed along the superior border of the pubic ramus bilaterally. This was done without opening of the tuberculous area, thus the possibility of contaminating the graft with the tubercle bacillus was avoided. The end result shows an excellent bony bridge between the two sides at the end of 4 post-operative years.

CARLO SCURRI, M.D.

FRACTURES AND DISLOCATIONS

Treatment of Fractures and Pseudarthroses with Marrow Nailing. SVEN KIRSCHNER. *Ann. chir. gyn.* 1947 36 77.

Kirschner's medullary nailing has been used for suitable cases at the Finnish Red Cross Hospitals since the year 1944. The medullary nail has been resorted to, however, only in such cases in which retention performed in some other ways would have involved difficulties. A total of 93 medullary nailings has been performed (47 recent fractures, 34 pseudarthroses, and 12 osteotomies and joint resections). V-shaped medullary nails, made both in Finland and Sweden, have been used and they have

proved satisfactory. On the contrary the chromium plated Kirschner wire which has also been used in ulnar fractures, has turned rusty and has often irritated the bone considerably. For the femoral fractures the average hospitalization was 39 days. The mobility of the joints was satisfactory except in a few cases. In practically all of the femoral fractures the mobility of the knee joint has been at least from 180 to 60 degrees. The range of movement of the other joints has not been restricted. With regard to the tibial fractures, the mobility of the joints has also been unrestricted and this was also true of the range of movement of the other joints.

The various cases of osteotomy in this series are best comparable to recent fractures. The fragments were brought to a desired angle by means of a medullary nail. In all of the completely treated patients a satisfactory result occurred. In 3 cases of knee-joint resection resort was made to medullary nailing. In 2 of them osseous healing took place whereas in 1 there was no consolidation.

The author treated 34 patients with pseudarthroses by means of medullary nailing and in 23 of these there was consolidation while in 9 there was none. The majority of the cases of pseudarthrosis were war injuries and the duration of the condition varied from 6 months to 2½ years. There were 12 femoral pseudarthroses altogether. The site of the pseudarthrosis was exposed in all of the cases, the inter-mediate connective tissue was removed, and the bony ends were sown lightly either straight or obliquely so that partial or entire removal of eburnated bone has taken place. If some of the sclerotic osseous tissue remained a channel was bored through it for the medullary nail. In addition, the bony ends were firmly united in several cases by means of a metal wire.

The poorest results were obtained in nailing pseudarthroses of the ulna and radius. In these cases Kirschner wires were used. These wires were so weak that they could prevent only outward dislocation of the fragments, whereas they were not capable of resisting the tendency of the fragments to angulate.

In summarizing these results, the author advocated resection of the pseudarthrosis and the surfaces of the bony ends by oblique sawing. If the marrow cavities are not open they should be bored. The animal experiments performed by Kuntzsch led him to the conclusion that the medullary nail does not occasion permanent injury to the marrow. However there were no clinical symptoms in these cases. There are only 2 reports on true fat embolism with clinical symptoms in connection with medullary nailing but it was not possible to decide whether the fat embolism occurred as a result of the fracture itself or of the reduction, or whether it was caused by the medullary nail itself. The most suitable cases for nailing are the transverse, short oblique and spiral fractures of the diaphysis. The choice of length and thickness of the nail is determined by the width and location of the narrowest passage of the bone.

In the technique of medullary nailing it is essential that the fracture be well reduced before the nailing as even the slightest dislocation may render impossible the driving of the nail from one medullary cavity into the other. In the reduction of femoral fractures with overriding the author has resorted to wire traction for a few days until the shortening had disappeared. In femoral nailing straight nails are used which are inserted from the upper end of the large trochanter. The patient is placed in lateral position on the extension table with the fractured femur upward. The femur must be bent considerably in the hip joint, so that the top of the trochanter is directed backward against the axis of the body. In thin patients the top is easily palpable. In obese it may be more difficult to find.

In the back edge of the top of the trochanter a sufficiently large hole is made for the insertion of the leader. The position of the leader is checked by roentgenograms to be certain that it is properly located in both the marrow cavities and to determine the length of a suitable medullary nail. The medullary nail is driven along the leader far enough to ensure that it reaches the medullary cavity of the other fragment. The leader is then removed. The nail is subsequently driven in so that only 3 or 3 cm. of it projects from the bone. In the tibia the nail should be inserted 1 cm. above the ankle when the fracture is located in the lower part of the tibia, in order to provide sufficient support. As the nail is inserted from the side it must bend somewhat when inserted. In cases in which the marrow cavity is quite extensive, use has been made of two thinner nails placed side by side instead of one single thick nail which would be too rigid. Care should be taken to prevent the second nail from driving the first nail too far. Occasionally an open reduction must be performed before the nail is inserted. This was the case in a femoral fracture and in several cases of radial and ulnar fractures. The opening of the site of fracture did not cause any complications in these patients.

The nails have remained in the bone until complete osseous healing has taken place usually from 3 to 6 months. If one tries to extract the nail before 3 months have elapsed difficulties may develop, especially when the fracture is in the femur. After 6 months, however, the nail lies so loosely in the marrow cavity that its removal does not require force.

C. FRED GOERING, M.D.

A Method for the Treatment of Fractures of the Expanded Ends of Long Bones. H. K. CHRISTIE.
Austral N Zealand J Surg., 1947 17 29

In the treatment of fractures of the expanded ends of long bones the author uses a "C" clamp with sharp pointed jaws which engage the bone fragments through stab wounds in the overlying soft tissues. The jaws have rounded expanded "shoulders" to prevent their sinking deeply into the bone. He states this clamp is a "logical expansion of Bohler's redresser" and of Steinmann's pins.

The objectives of the device are (1) to reduce and hold reduced the spongy bone fragments around the large joints and (2) to permit immediate movement of the affected joint.

The clamp is applied under roentgenoscopic control. Reduction is carried out with traction (often with temporary use of Kirschner wires and weights). The jaws are inserted through small incisions and the pressure is applied directly to the bone and not to the soft parts. The fragments are thus pressed together and held securely.

Photographs and a table representing 5 cases of fractures about the knee joint are presented. Good function appears to have been obtained in this small series. The author believes that his method has advantages over internal fixation and over methods which require prolonged immobilization of the joints.

NEWTON C. MIZAD, M.D.

Intramedullary Metallic Fixation in the Treatment of Fractures of the Long Bones; Results in 28 Cases (L'infibulamento metallico midollare nelle fratture delle ossa lunghe: contributo di 28 infibulamenti) E. BIALAK *Chirurgia* 1946 1 216

The author gives a résumé of the bibliography of the Kuntscher method of intramedullary metallic fixation of fractures of the long bones. Kuntscher's original presentation was given at the Sixty-fourth German Surgical Congress in 1940.

A description of the operative technique is given in some detail illustrating briefly the method used by the author on various bones.

A report is made in this article of 28 operations done on 24 patients. A number of before and after roentgenograms illustrate the article. The possible dangers and complications of this method are discussed and presented clearly. They are:

- 1 Osteomyelitis, a severe complication
- 2 The use of too large a nail which splits the shaft.
- 3 The use of too small a nail which permits angulation and disalignment.
- 4 Fat embolism.
- 5 Technical difficulties of insertion or removal of the nail.

The author has been using a round nail instead of the V shaped nail of Kuntscher with a smaller diameter and advocates some postoperative immobilization in plaster. Infection occurred in 3 of the cases presented.

CARLO SCUDERI, M.D.

Operative Treatment of the Pseudarthroses of the Neck of the Femur (Traitement opératoire des pseudarthroses du col du fémur) P. LANCE. *Rev orthop. Par.*, 1947 33 363.

If one wishes to discuss the essentials of the problem certain factors must be considered in the selection of one or two operative techniques for the treatment of pseudarthroses of the neck of the femur. Besides the age of the patient these factors are (1) the age of the pseudarthrosis (2) the roentgenologic appearance of the bony fragments especially of the femoral head (3) the degree of

displacement and reduction, (4) and the previous treatment (an attempt at nailing or not)

In pseudarthroses less than 3 months old for which no treatment or inadequate treatment has been instituted the roentgenologic appearance of the head and neck cannot be considered conclusive. If perfect reduction can be accomplished nailing is indicated. If on the other hand reduction is only fairly good or impossible, other procedures must be preferred. If the patient is young and in good condition, an intra-articular arthroplasty or simple refixing of the fragments, followed by nailing may produce consolidation of the lesion. If the patient is 60 years old or more an arthroplasty is the procedure of choice.

In an old pseudarthrosis the pathologic process is arrested. If there is necrosis of the femoral head, or if the vitality of the head is in question, a Whitman or Colonna type of arthroplasty is necessary. A bony shelf is added to the procedure when the neck is short or thin, when the roof of the acetabulum is effaced, or when the stabilization of the neck is questionable. If the femoral head appears normal with only very little displacement of the fragments, intertrochanteric osteotomy is advisable, but if there is atrophy of the head associated with great displacement of the fragments an open osteotomy or arthroplasty are the procedures of choice.

The very old pseudarthrosis in which the neck has completely disappeared can be treated by an intra-articular operation if the patient is in good condition, or by arthrodesis with nailing if the patient is very old. If arthrodesis by nailing does not always produce a complete ankylosis, it, nevertheless, stabilizes the hip and allows the patient to walk. For this reason it deserves to be included in the operative techniques dealing with pseudarthroses.

If the nailing has been accurately executed on a satisfactory reduction and pseudarthrosis occurs after the nailing the pseudarthrosis is then, almost always, the result of partial necrosis of the head. Removal of the nail is imperative and must be followed by osteotomy or arthroplasty. The latter procedure is to be preferred when complete necrosis of the head exists.

Pseudarthrosis may have occurred because of incorrect nailing due to an error in direction or a poor reduction. If the lesion is relatively recent, the whole procedure can be repeated, provided one is certain that there is no anatomical contraindication.

If the fracture is old and pseudarthrosis has been present for several months, one is justified in attempting an arthroplasty or an osteotomy according to the condition of the head and the position of the fragments.

One hundred and three pseudarthroses of the neck of the femur have been surgically treated by the author. Arthroplastic resection was carried out in 63 of them, without operative mortality. Fifty patients were available for follow-up study. Good or excellent results were obtained in 39, or 78 per cent. Nearly all of the patients obtained at least 40

degrees of flexion. Dislocation of the stump of the neck out of the acetabulum occurred twice.

The author stresses the fact that arthroplasty should not be considered a grave procedure which is contraindicated in old patients.

Thirty nine osteotomies have been performed by the author: 30 intertrochanteric, and 19 subtrochanteric, with 6 failures. The length of immobilization in a plaster cast constitutes a serious disadvantage of osteotomy. Limitation of hip motion is a common occurrence. However osteotomy must not be considered as a last resort, reserved only for old and bedridden patients, nor is it the ideal operation solving all the therapeutic problems inherent to pseudarthroses. If correctly executed and well indicated, intertrochanteric osteotomy will usually secure good, and sometimes excellent, functional results.

Pseudarthrosis following nailing of fractures of the neck of the femur is not a rare occurrence. Of a series of 100 cases of pseudarthrosis seen at the Cochin Hospital 16 cases occurred in patients who had undergone hip nailing. Necrosis of the head of the femur was observed 8 times. Resorption of the neck and defective nailing were also factors responsible for the occurrence of the pseudarthrosis.

All pseudarthroses occurring in patients under 70 years of age should be subjected to surgery unless serious organic conditions are present (diabetes, hemiplegia, or cardiac failure). On the other hand, one must be cautious in advising operation in patients over 70 years of age. Extra-articular procedures carrying the minimum risk should be selected.

As a rule, if the pseudarthrosis is compatible with the upright position and associated with a minimum amount of pain, one should refrain from operating.

If the patient cannot walk and the pseudarthrosis is rather recent, reduction and fixation by nailing may be attempted. If reduction is poor or impossible, arthrodesis with a nail is to be preferred to osteotomy which calls for longer immobilization.

The pseudarthroses following pathological fractures as seen in tubercles can be subjected to surgery if the patient is relatively young, in good general condition, and if the arthropathy appears as an isolated manifestation.

The accuracy in reducing and fixing the bony fragments constitutes the best prophylactic treatment against the occurrence of pseudarthrosis.

GERARD GAGNON, M.D.

Fractures of the Femoral Diaphysis in the Infant.
Results of Treatment (*Fractures de la diaphyse fémorale chez l'enfant. Résultats du traitement*).
FRANÇOIS TURRILLON. *Rev. orthop.* Par 1947 33 328.

This study is based on 337 fractures of the femoral diaphysis in the infant, 171 of which were treated by simple orthopedic reduction 87 by traction with the Kirschner wire 33 by traction in flexion (method of Godard) 13 by intramedullary fixation with the

Kuentscher nail, and 30 by open reduction with various procedures. The best results were procured by the flexion pelvi-cruro-jambière method as described by Godard in 1941. By this method a Kirschner wire is passed through the tuberosity or through the condyles and the traction by means of this wire and the rest for the foot are regulated by means of a special attachment to the ordinary fracture table so as to maintain the knee flexed at 135 degrees while the fracture is being reduced and the leg encased in the plaster cast. If need be the reduction is assisted by means of Godard's modification of the Herzog lever. The results obtained by Godard's method are even more striking in that the material included just those cases which would be difficult to treat by other methods. The article is accompanied by several illustrations.

If the cases without initial displacement are omitted, the results with simple closed reduction and plaster of Paris immobilization were good in 34 per cent, indifferent in 35 per cent and bad in 31 per cent and with the Kirschner method good in 45 per cent, indifferent in 35 per cent, and bad in 20 per cent. With the Godard method on the other hand the results were good in 74 per cent, indifferent in 17 per cent and unsatisfactory in only 9 per cent. The Godard method, therefore, has come to be regarded as the method of choice for the cases of displaced fracture which admit of orthopedic reduction.

In the cases treated by open reduction the best results were secured by the temporary cerclage method of Leveuf. In this procedure the bone is encircled by a small wire ligature which is then led through a small metal tube both ends are thus fixed and drawn taut by a mechanism attached to the other end of the tube. While this method can of course be applied only to spiral fractures it has the advantage of cancelling a second operation to remove the fixation material as at the end of the period of fixation the mechanism can simply be loosened and the ligature or ligatures withdrawn. For the transverse fracture the Kuentscher pin is preferred the plaster immobilization is thus avoided and the operation for removal of the intramedullary pin is insignificant. This intramedullary method is even preferred to the simple osteotomies.

JOHN W. BRECKMAN M.D.

Intertrochanteric Fractures of the Femur. A Survey of Treatment in Traction and by Internal Fixation. MATTHEW CLEVELAND, DAVID M. BOWORTH, and FREDERIC R. THOMPSON. *J. Bone Surg.*, 1947 39 1049.

The authors survey 133 consecutive cases of intertrochanteric fractures of the femur and present follow-up studies on 94 per cent of the patients. The series consists of (1) a group of 38 patients treated mainly by traction and (2) a group of 95 patients treated by internal fixation. The final outcome in the cases of all patients treated by internal fixation is known.

The average age of the patients who were treated

by traction was 78 years and of those treated by nail fixation 75 years.

Of the various types of internal fixation the angled one-piece nail and plate described by Jewett in 1941 proved to be most satisfactory. The following changes in its structure were made: the vertical flange on the deep surface, at the junction of the plate and the nail was removed. This flange caused increased comminution of the trochanteric structure of the femur in several instances as the nail was driven home. In several other instances increased comminution was due to attempts at cutting a trough for reception of the nail. A passageway for the Kirschner wire, used as a guide, was eliminated as this weakened the nail or made it more cumbersome. Reinforcement of the junction of the nail with the plate was secured by thickening the plate at this point. The casting of nails with three angles (130 degrees, 140 degrees, and 150 degrees) permitted close coaptation of the plate to the femoral shaft, regardless of the angle of the neck at the time of reduction without the necessity of bending the apparatus. The casting of a nail of each angle in a normal length and in a short length obviated overdrive in severely comminuted fractures. The removal of the streamlined head and its replacement by a ledge behind the head of the nail for application of a hook extractor, facilitated removal when threads in the base of the nail were stripped and a threaded puller could no longer be used. Such a nail can be used successfully in even the severely displaced and comminuted type of para-trochanteric or intertrochanteric fracture with the added advantage of its being of great practical value in the difficult subtrochanteric type of fracture occurring high in the femoral shaft, and in that rare type of fracture in which both the neck and the trochanteric region are involved.

Both a surgical team and a roentgenographic team who are acquainted with the nailing procedure are necessary for the smooth and rapid handling of such cases.

A comparison of the end results in patients treated by internal fixation with those in patients treated by traction reveals the following:

1. With the use of internal fixation the hospital mortality was reduced to 12.6 per cent, as compared to a hospital mortality of 34 per cent after treatment with traction.

2. Severe senile mental deterioration occurred in 11 per cent of the patients following internal fixation as compared with an incidence of 11 per cent in the group treated by traction.

3. The survival rate at the end of 4 years among the patients operated upon was 17 per cent higher than that of the group upon which operation had not been performed.

4. All complications were reduced sharply in those patients who were subjected to internal fixation.

5. Although union of the fracture took place in all survivors, the functional result in those treated by internal fixation was vastly improved.

RUDOLPH S. REICH M.D.

The Indications and the Postoperative Care of Fractures of the Neck of the Femur Treated by the Use of the Putti Screw (Contributo alle indicazioni e al trattamento postoperatorio dell'avvitamento alla Putti delle fratture del collo del femore) GORDO CATALANO *Polidivica sec chir* 947 54-137

The author believes that following the use of the Putti screw, the patient should be kept in bed but early mobilization of the articulations is recommended. No weight bearing should be permitted until evidence of bony union occurs, which takes a minimum of 6 months.

The early use of the leg in bed eliminates the need of physical therapy and also does not require special personnel for the management of these patients.

The author believes that only those patients which belong in group 3 of Pauwel's classification should be subjected to internal fixation by means of a Putti screw. He recommends immediate subtrochanteric osteotomy for all patients that belong in Pauwel's group III.

CARLO SCUDERI, M.D.

Dislocation of the Semilunar Bone with Special Consideration of an Atypical Case (*Luxaciones del semilunar con especial consideración de un caso típico*) CIRILO GONZÁLEZ SÁNCHEZ *Ciruj per locomotor* 1947 4-243.

Six cases of dislocation of the semilunar bone are reported by the author. In one instance an anterior dislocation was combined with rotation of the displaced bone around its longitudinal axis so that the bone assumed the position of supination. The presumptive clinical diagnosis was corroborated by roentgenograms taken in three directions. An open reduction according to Boehler's method was employed with good results.

Of the 6 cases of dislocation of the semilunar bone 3 were combined with a fracture of the scaphoid bone and 2 of them were complicated by a fracture of the apophysis of the styloid process of the radius while in the third case the posterior portion of the lower end of the radius was fractured.

A triangular deformity of the dislocated semilunar bone is a characteristic finding in the roentgenograms.

JOSEPH K. NARAY, M.D.

ORTHOPEDICS IN GENERAL

The Medullary Nail: Presentation of a New Type and Report of a Case. DANA M. STREET, HARVEY H. HARRIS, and BRUCE J. BREWER. *Arch. Surg.* 947 55-433.

The authors believe that the Kuntscher nail supplies fixation of shaft fractures which is analogous to hip fixation by nails. The Kuntscher method originally required open reduction, but was later done under fluoroscopic control the nail being introduced through the femoral trochanter, or into other bones through a hole in the shaft. The double diverging nails of Nasta, introduced through a window in the cortex, were designed to take up the play in those

parts of the medullary canal where there was too much width for the nail to be stable.

The authors describe 4 cases in which an intra medullary nail was used, the nail being different from those used previously in that it was diamond shaped in its cross section.

The advantages of the intramedullary method over previous methods of internal fixation are, in the opinion of these authors as follows: (1) fixation is solid and no cast is necessary; (2) motion of the adjacent joints can be started immediately; (3) no stiffness or atrophy resulting; (4) the patient needs to remain in bed only a short time with early ambulation. The authors feel therefore that this method would be valuable for aged patients; however they do not present any aged patients in their short series. They also believe the method is useful when there is an associated fracture into an adjacent knee or elbow. It is recommended especially for the treatment of comminuted fractures with multiple transverse fracture lines. The fragments are threaded on the nail like beads. If the fracture is near the bone end the nail does not prevent lateral displacement, and is therefore not indicated. This method is contraindicated in compound fractures because of the danger of widely spreading infection.

Callus formation in 3 of the patients was as rapid as that seen after closed reductions. In one case the callus was definitely delayed.

The authors believe that open reduction is safer as it diminishes the risk of fat embolism and this method is easier than inserting the nail at the trochanter and controlling the reduction under the fluoroscope.

The advantages of the diamond shaped nail lie in its strength, and in the fact that it contacts the inner surface of the canal at only two points (as viewed in cross section) and more of the canal is therefore undisturbed. The choice of stainless steel was due to the need for strength and resiliency for fracture or bending of a nail would be a difficult complication to manage. The authors do not recommend this method as a routine means of supplying internal fixation to shaft fractures. NEWTON C. MASON, M.D.

A New Plate for Osteosynthesis. HERBERT SÖLJAND. *Acta chir scand.*, 947 66-178.

Some form of internal fixation is desirable in many types of fracture and most workers find that it is relatively easy to apply and mechanically firm. Abnormal mobility at the fracture site inhibits callus formation while pressure of the fractured surfaces against each other seems to encourage callus formation. The Lane plate may be applied to an anatomically perfectly replaced fracture but on tightening the screws a small diastasis appears. This cannot readily be corrected and the defect persists and may increase as absorption takes place at the fracture site. The rigid fixation prevents approximation of the fracture fragments. The occasional occurrence of delayed union or nonunion when a plate is used seems thus to be on such a physiologic basis.

The author presents a stainless steel plate so per cent lighter than Lane's plate and pliable so that it can be fitted to contour. There is a slot to replace the screw holes, which takes the usual type of screw and permits insertion of the screws at any point desired so that fissures can be avoided and most advantageous fixation secured. The plate affords firm immobilization even after the screws in one fragment are slightly loosened to permit guided gliding of the fracture ends toward each other and maintains constant bony apposition which encourages callus formation. If a screw breaks or goes askant another can be placed beside it without moving the plate.

Röntgenographs of a fracture in a previously osteomyelitic femoral shaft show measurable gliding of the screws in the slot during the course of healing with maintenance of axial position and good callus formation. FRANCIS E. BRENNER, M.D.

Paradoxical Contractions of the Muscles in the Course of Obstetrical Paralysis of the Brachial Plexus. Synergistic Disturbances (Contractions paradoxales des muscles au cours des paralysies obstétricales du plexus brachial. Troubles de la synergie) JACQUES LEVEY, POL LE CORRE, J. LEREVY, and J. LERICQZ. *Rev. orthop.* Par. 1947 33 305

Clinical study and myographic tracings of the action currents in obstetrical paralysis of the brachial plexus have uncovered marked disturbances of muscular synergy. Normally when a muscle contracts under volitional influence its antagonist relaxes and the action current measured on the latter muscle remains unchanged in intensity or even falls below normal. By observing the muscles involved in these obstetrical paralyses during the period of recuperation—the initial stages of this form of paralysis have not as yet been studied—many hitherto unexplained phenomena of muscular action in patients with this condition have been found. The arm cannot, as a rule, be raised above the level of the shoulder, yet passive manipulation of the arm proves that this movement is perfectly free and that the joints are normally mobile.

This phenomenon has previously been dismissed with the explanation that the antagonistic muscle—in this example the deltoid—is too weak to raise the arm any farther. Yet in obstetrical paralysis the muscles are seldom completely paralyzed. When the child is instructed to raise the arm the deltoid begins to contract normally but its antagonists principally the *teres major* and the *latissimus dorsi*, also spring into view, as though they were producing a functional ankylosis of the shoulder joint. This paradoxical contraction of the antagonist can be measured with the myograph for very small movements. Also some contraction can be detected in other muscles, such as the *pectoralis major* and the *subscapularis*.

Identical paradoxical behavior has also been demonstrated with the myograph in the antagonists, the *subscapularis* versus the *infraspinatus*, and in

the *brachialis anterior* and *biceps* versus the *triceps*. Such synergistic dysco-ordination has also been registered by the myograph in the pronator and supinator muscles of the forearm; however the difficulties of myographic study of the forearm have so far prevented the establishment of any definite conclusions. JOHN W. BRENNAN, M.D.

Palliative Operations in Traumatic Palsies of the Upper Limb (Operations palliatives dans les paralysies traumatiques du membre supérieur) M. GUTHRIE SMITH and R. MICHEL D'AUBIONÉ. *Rev. orthop.* Par. 1947 33 390.

A large number of traumatic palsies of the upper limb cannot be readily cured by suture or neuroplasty but in many cases the incapacity can be diminished or even abolished by palliative operations.

There are five main indications for palliative operations in the upper limb: (1) re-establishment of abduction, (2) conservation of the mobility of the elbow, (3) re-establishment of extension of the wrist and fingers in radial palsies (this constitutes the major indication), (4) re-establishment of opposition of the thumb in lesions of the median nerve, and (5) supination, not so much to restore the function but, at least, to place the forearm in a favorable attitude for the use of the hand.

A certain number of principles or rules are essential in effecting tendon transplantation. Before anastomosis is attempted the function of the joints to be moved by the transplanted tendons must be normal or close to it; all deformities should be corrected and retraction of the antagonistic muscles should be abolished. Much reflection must be done in selecting the muscles for transplantation. These muscles must be healthy and strong enough to assure the necessary contraction. It is not necessary for the muscles to have a function similar to that of the paralyzed muscles. Moreover the use of muscles with an opposite function has an advantage: it re-establishes the equilibrium of the powers. However one must not carry this principle too far and jeopardize the stability of the proximal joints.

Certain technical and mechanical precautions must be taken to obtain a good result with a tendon anastomosis: the reactivating muscle must be of similar strength and have a course comparable to that of the tendons that it will move; the bed in which the transplanted tendon is placed must be soft and healthy and allow easy mobilization.

Experience has shown that when one is dealing with palsies of the shoulder and scapular girdle, fixation operations produce the best results. Palsies of the wrist and hand are best treated by restoration and transplantation operations.

At the shoulder arthrodesis, if not the operation of choice is at least the surest solution. In skillful hands transplantation of the *trapezius* muscle for palsies strictly limited to the deltoid muscle has given excellent results.

In cases of isolated palsies of the *serratus magnus*, transplantations have also given fine results. Scap-

Fig. (Guilleminet and D'Anghel) Transplantation of the pronator teres to the extensor carpi radialis longus and brevis. The pronator teres tendon is drawn by the fine forceps through the holes made in the extensor carpi radialis longus and brevis tendons, to which it will be sutured.

ulopexy is, however, more often preferred, especially if the rhomboids and part of the trapezius muscles are deficient. The loss of the trapezius muscle constitutes an absolute handicap to any restorative surgery.

At the elbow, transplantation of the epitrochlear muscles is a good operation for restoring some degree of active flexion. Transplantation of the pectoralis major on the biceps is the next best. The use of a mechanical device is to be preferred to arthrodesis at the elbow because it will allow a certain degree of motion.

Transplantations to restore active supination produce variable results. One must be satisfied in securing the forearm in a position compatible with function.

The radial palsy can be overcome almost perfectly by tendon transplantations. Extension of the hand is restored by transplanting the pronator teres muscle to the extensor carpi radialis longus and brevis. Extension of the fingers is restored by transferring the flexor carpi ulnaris to the extensors. Abduction of the thumb must be treated separately by transplanting the palmaris brevis or a superficial flexor if the former is absent, to the long abductor and extensor brevis. The palmaris longus must be left in place as a stabilizer of the hand.

If one aims at reactivating the tendons, arthrodesis of the wrist will make all the flexor and extensor tendons of the wrist available for anastomosis.

The function of opposition of the thumb, the loss of which is the most serious and most common sequelae of palsy of the median nerve, can be corrected by fixing the thumb in permanent opposition with an intermetacarpal graft or by arthrodesis. Also a new opponens muscle can be made with one of the superficial flexors or the flexor carpi ulnaris. The new opponens muscle must be reflected at the level of the pisiform bone and fixed to the base of the first phalanx of the thumb.

Less often one will be called upon to correct a palsy of the interossei by using the superficial flexors, or a palsy of the flexors of the fingers and thumb by

transplanting the brachioradialis or flexor carpi ulnaris, or even by tenodesis.

The authors developed a technique of their own to correct the paralyzed extensors of the hand and fingers and have used it in 36 cases during the last 5 years. A 6 cm. incision is made in the middle third of the forearm between the brachioradialis and flexor carpi radialis. The pronator teres tendon is identified and detached from its insertion on the radius. It is obliquely introduced into a hole in each of the extensor carpi radialis tendons to which it is fixed with stainless steel wire. The pronator teres must be fixed under moderate tension the hand being held in slight dorsal extension. A 7 cm. longitudinal incision is made on the anterior surface of the wrist immediately lateral to the flexor carpi ulnaris without crossing of the flexion crest.

The flexor carpi ulnaris tendon is detached from the pisiform bone and liberated for a distance of about 10 cm. The skin is undermined. Through the same incision the palmaris brevis tendon is isolated and detached from its insertion. If the latter is absent, the superficial flexor tendon of the third finger is isolated and divided just above the annular ligament. The distal end is buried in the flexor profundus to prevent the formation of adhesions.

A 3 cm. transverse incision is made just above the flexion crest of the wrist. The skin of the forearm is undermined and the proximal end of the palmaris brevis tendon or the superficial flexor of the middle finger is caught and introduced into the long abductor and extensor brevis tendons of the thumb, which is held in complete abduction and extension. Two stainless steel wire sutures hold the transplanted tendon in place.

A 3 cm. oblique dorsal incision is made 4 finger breadths above the wrist. The extensor tendons of the fingers and the extensor pollicis longus are exposed. The flexor carpi ulnaris tendon is then brought into this incision. The thumb is extended and abducted, the first phalanges of the fingers are held in complete extension with a tenotome, an aperture is made in a direction obliquely downward and outside in the fifth, fourth, third, second and first extensor tendons. A fine hemostat is introduced in a reverse direction through the holes, and the flexor carpi ulnaris tendon is caught and drawn through the holes of all of the tendons. The transplanted tendon is sutured with stainless steel wire to the extensor pollicis longus and to the extensor tendons of the index and third fingers.

After closure of the wounds, the hand and first phalanges of the fingers are kept in forced extension in a plaster cast. The thumb must be kept in complete abduction and extension.

The authors review their results in 36 cases. In 23 transplantations of the pronator teres to the extensor of the radius, the extension of the hand was incomplete in only 1 case. The flexion of the wrist remained limited to an important degree in only 3 cases. The flexion of the fingers was limited in only 4 cases.

Fig 2 (Gulleminet and D Aubigné) Palmar incision. Dissection and section of the flexor carpi ulnaris tendon. Drawing the palmaris brevis tendon through the long abductor and extensor pollicis tendons of the thumb.

Extension of the thumb was normal in the 10 cases in which transplantation was carried out separately for the extensor pollicis longus (flexor carpi ulnaris) and for the abductor and extensor brevis (palmaris brevis). In the 16 other cases, 5 showed normal extension of the thumb 10 limited extension and 1 definitely insufficient extension.

Following radial palsy it is possible to restore almost normal motion of the hand and fingers by tendon transplantations. The best results are only slightly inferior to those obtained following perfect suture of the nerve while the more inferior results are far superior to those following incomplete regeneration of the nerve. The patient is allowed to use his hand in a period of from 1 to 2 months following surgery.

In the light of these facts, the authors discuss the indications for palliative operations with regard to curative surgery, such as suture or nerve graft. The authors believe that the functional value of the hand following complete regeneration of the radial nerve is superior to that following a successful transplantation.

A good result can be obtained by suture of the radial nerve in from 50 to 80 per cent of the war wounded. Among civilians, the proportion would undoubtedly be higher.

The indications for immediate tendon transplantation are loss of nerve substance of more than 6 cm. and lesions which are a year or more old. The indications for arthrodesis of the wrist are exceptional in simple palsy of the radial nerve, but the procedure is imperative when it is necessary to provide tendons for purposes of transplantation.

Chondromalacia Patellae. JACOB BROMITSKY, J Bone Surg 1947 29 931.

The term chondromalacia patellae applies to a circumscribed degeneration of the articular surface of the patella as evidenced by softening, fibrillation with eventual fissuring and erosion of the cartilage. Although trauma is the primary exciting cause, a predisposed constitution and peculiar mechanism of the knee joint play important roles in the etiology of the lesion.

The earliest detectable lesions are most frequently located on the medial facet of the patella, less frequently in the center and occasionally on the lateral facet. In the most severe cases the entire articular surface may be involved. Wilberg explained that this distribution of the lesions is based on the peculiar anatomy of the patellofemoral joint.

The history is that of chronic knee discomfort of varying degrees of severity. The usual complaints are pain, weakness and a tendency of the knee to buckle. This is noted especially when climbing a hill or on walking up or down stairs. Often there is difficulty in fully extending the knee and momentary locking may be present. There may be effusion into the joint, actual locking may occur when there are loose bodies within the joint frequently the knee aches, especially after sitting for some time in one position, there may be some morning stiffness, crepitation of the patella may be pathognomonic, pain on pressure over the patella is often elicited, there may be fluid within the joint, and atrophy of the thigh muscles. In the early stages of the condition roentgenograms are usually negative.

No patient was operated upon until conservative therapy had failed to give relief. The operations were chondrectomy in which the degenerated cartilage was shaved or the same procedure in which the patellar surface was covered with synovial membrane patelloplasty in which the entire patellar cartilage and subchondral bone were removed with a saw the bony shell then being covered with synovial membrane or complete excision of the patella. The best results were obtained either by chondrectomy or patellectomy.

DANIEL H. LEVINTHAL, M.D.

The Orthopedic Value of the Various Amputations of the Foot (Valor ortopedico de las distintas amputaciones del pie) MARIO OLIVERAS DEVERA *Ciruj. per locomotor* 1946 3: 290.

Various foot amputations are discussed and evaluated in this article. The Lisfrance, Chopart, Ricard, Souligoux, Syme, and Pirogoff methods are specifically singled out and appraised from an anatomic, physiologic, and particularly a prosthetic viewpoint. It is thought that Lisfrance's amputation at the metatarsal articulation gives the best

results according to the criteria advanced, and, when possible it should be employed.

Chopart's amputation is considered a poor operation because the end-results often produce pain in the heel, the anterior scar is extraordinarily sensitive, and interference with the circulation produces ulceration. The Ricard operation gives a very satisfactory result despite its similarity to the Chopart operation. It is more like an astragalectomy and as such produces a better terminal stump than the classic Chopart procedure. Souligoux's technique is more mutilating than Chopart's as it sacrifices the anterior tuberosity of the calcaneus and makes the adaptation of prostheses both difficult and intolerable.

The author has had little experience with the Syme operation, although he believes the operation is good because it permits good prostheses. The Pirogoff operation is considered satisfactory provided the divided part of the calcaneus can be made to unite firmly to the tibia. Supramalleolar operations are best from a prosthetic viewpoint if the lower third of the leg is employed.

STEPHEN A. ZIEGLER, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Carotid Body Tumor in Association with Carotid Sinus Syndrome BARTON McSWAIN and FRANK C. SPENCER. *Surgery* 1947 22 223

A 15 year old male entered Vanderbilt University Hospital, Nashville, Tennessee, complaining of fainting attacks and a lump in the neck. Physical examination showed a firm, nontender mass about 3 cm in diameter just posterior and inferior to the angle of the left mandible. Pressure upon this mass caused pallor, loss of consciousness and a drop in the blood pressure. The mass was removed under intratracheal anesthesia, along with a portion of the cervical sympathetic chain and the superior laryngeal nerve to which the tumor was adherent.

There were no attacks subsequent to surgery. Two and one-half years after excision a mass was felt in the region of the bifurcation of the right common carotid artery. No symptoms could be elicited by pressure. There was no recurrence of the carotid body tumor removed from the right side.

A second patient was found to have a tumor mass similarly located on the left side. She gave a history of many fainting attacks which had occurred 8 years prior to her admission to the hospital. These attacks had become less frequent and had subsequently ceased spontaneously. The mass was excised. Four months after the operation no symptoms had been noted and there was no evidence of recurrence of the tumor mass.

EDITH B. FARNSWORTH, M.D.

The Painful Symptoms of Arterial Elongation (Les symptômes douloureux des dolicho-artères) RENE LERICHE. *Presse méd.*, 1947 57 641

In 1942 the author first described the existence of dilatation and elongation of certain arteries without visible cause. Since then he reported 2 more cases of this condition, and more recently 2 additional instances have been observed by others. Surgeons who operate on the blood vessels have yet to correlate the condition with a definite clinical syndrome. Consequently the diagnosis requires arteriographic or operative confirmation.

An additional case is reported in detail.

A 68 year old male complained of pain in the right iliac fossa of 6 months duration. Appendectomy was performed. At operation an indurated retroperitoneal mass was noted beneath the appendix. Three days after operation the patient began to have persistent severe pain below the right ankle in the upright position, relieved by elevation of the leg and holding it in slight flexion. Examination revealed a strong posterior tibial pulse and a normal oscillometric index in the supine position but the pulse faded and oscillations stopped in the upright position.

The author made a tentative diagnosis of arterial elongation involving the right iliac arteries with

Fig. 1 (Leriche) Retrograde arteriogram by injection of right common femoral artery. Marked tortuosity and elongation are apparent in both common iliac arteries and their branches.

linking in the upright position. In order to confirm the diagnosis, direct aortography was attempted but only the superior mesenteric artery and its branches were visualized. A retrograde arteriogram was then taken through the left femur. Elongation and tortuosity of the left common iliac artery and its branches was demonstrated but the right iliac system did not fill with the opaque medium.

Operation was performed consisting of right lumbar sympathectomy and exploration of the right iliac vessels. The common iliac artery was found to be tortuous and made a bend which brought it under the peritoneum behind the cecum. When postoperative recovery had taken place another retrograde arteriogram was taken through the right femur. The marked tortuosity of both iliac systems was clearly demonstrated (Fig. 1).

In conclusion the author points out that this condition may provide the explanation for certain unexplained right iliac fossa pains in elderly patients. Furthermore, he states that he saw 2 patients in the past with epigastric pain with no basis other than dilatation of the retropancreatic aorta. The etiology and pathogenesis of arterial elongation remain obscure.

THEODORE B. MARRAS, M.D.

Vascular Responses in Man to Ligation of the Inferior Vena Cava. C. THORPE RAY and GEORGE BURCH. *Arch. Int. M.* 1947 80: 587

Observations were made on 12 patients in whom the inferior vena cava had been ligated in the treatment of pelvic thrombophlebitis. Immediately after ligation the pressure in the dorsal pedal veins was markedly elevated in all but 1 patient. There was a gradual decline in venous pressure towards normal but it returned to within the maximum limits of normal in only two instances. There was no relation of venous pressure to the degree of edema or to section of the sympathetic nerves. The pressures in the ante-cubital veins were normal but in 5 of 6 patients there was an elevated pressure in the superficial low abdominal veins. An interesting factor was the absence of abnormal dilatation of the veins of the legs and the feet even in the presence of pronounced venous hypertension.

A quantitative study of the variations in volume of the tips of the fingers and toes was performed plethysmographically. The volume of pulse deflections in the toe tips was reduced immediately after operation to a mean value of 1.3 cubic millimeters per 5 cubic centimeters of part, which increased with time to mean values of 2.7 and 3.0 cubic millimeters. Section of the sympathetic nerves resulted in a greater mean value (5.5 cu. mm.) immediately after operation.

The rate of water loss from the right index finger tip, right second toe tip, right pretibial area, and the volar surface of the right forearm was measured quantitatively in 5 patients. There were no significant disturbances in water loss in a comfortable environment nor in a hot and humid one, the rate of the water loss increasing under the latter conditions.

The plasma protein content was determined in 7 patients at varying intervals after ligation. The protein levels tended to be slightly higher than normal with mean values of 4.8 gm. of albumin, 2.6 gm. of globulin and 7.4 gm. of total protein per hundred cubic centimeters. The range for total protein was 5.3 to 10.6 gm. per 100 cubic centimeters.

Measurements of the pressure in the subcutaneous tissue in the pretibial region were made in 6 patients. The tissue pressures rose after vena cava ligation to mean values of 45 and 50 mm. of water respectively. Tissue pressure tended to vary directly with the venous pressure and inversely with the degree of the edema.

Clinical observations revealed functional capacity of the lower extremities, normal skin temperature, normal color, texture, and nail growth. Two patients manifested no edema either before or after the operation. Edema was present in the remaining 10 patients and varied in severity from mild to extreme, but disappeared within 2 months after operation in all but 3 patients. This disappearance of the edema occurred without a concomitant fall in venous pressure. In only 3 patients did the edema persist for as long as 8 months.

The veins of the feet were small, varicosities were limited to minute veins of the skin. The superficial veins of the abdominal wall and gluteal region and also the long thoracic vein became dilated to form an unusually prominent network. The direction of blood flow was invariably cephalad in these veins of the trunk.

Clinical and physiologic observations failed to reveal any detrimental effect from ligation of the inferior vena cava because of circulatory adjustments which are apparently adequate but not all clearly understood. THORPE R. B. MARRIS, M.D.

The Use of Anticoagulants in the Surgery of Aneurysms and Arteriovenous Fistulas. With Particular Reference to Dicumarol. HARRIS B. SEIDMANN, JR., DAVID I. ARAMSON, and HERBERT H. LAMPERT. *Surgery* 1947 19: 10.

Inasmuch as the reported experimental and clinical data regarding anticoagulant therapy in arterial surgery are limited to the use of heparin alone, the authors believe it is desirable to record their experiences with a group of patients in whom some type of reparative surgery was attempted on a peripheral aneurysm or arteriovenous fistula, and in whom heparin or dicumarol was used either alone or together. The authors discuss the methods and means of control of the therapy employed, the general results, and complications encountered, and they demonstrate that reparative surgery of the peripheral arteries can be safely accomplished with anticoagulants given at the time of operation or before. They admit that the material was insufficiently controlled however to warrant drawing conclusions concerning the relative efficacy of anticoagulants in the prevention of thrombosis following arterial repair.

The clinical material consisted of some type of reparative procedure in 34 of 390 aneurysms and arteriovenous fistulas treated surgically. Among these cases 22 patients were given anticoagulant therapy for a more or less prolonged period of time. An additional patient received a single injection of heparin. The remaining 11 patients underwent simpler surgical procedures and received no anticoagulant therapy, but they did not serve as controls because the hazard of thrombosis was so much less. For the basis in the selection of cases for repair and the clinical results the reader is referred to an article by the senior author which is in press (*Ann. Surg.*). The methods employed for preserving the continuity of the vessel consisted of ligation and transposition of the fistula (13), lateral arteriorrhaphy (5), resection of a segment of the artery with end-to-end suture (10), and vein transplantation (6). Anticoagulant therapy was used infrequently in the first method, generally in the second, and routinely in the other two methods.

Crystalline heparin in aqueous solution was administered intravenously every 4 hours in 50 mgm. doses and continued for 3 days or until a satisfactory effect with dicumarol had been obtained. The first

injection was given at the time of operation. Dicumarol was administered only after an initial prothrombin level had been obtained. In general 300 mgm. were given the first day, 300 mgm. the second and 100 mgm. the third. Thereafter the dosage was determined on the basis of the daily prothrombin time and the drug was continued for about 3 weeks. From 20 to 30 per cent of the normal was chosen as the optimal prothrombin level based upon the Quick curve. The authors claim this value is roughly equivalent to a "clotting index" of 50. The method of Quick for the determination of prothrombin time is given in adequate detail. One member of the staff is given the responsibility for the readings and the dosages.

In 3 patients dicumarol was stopped within 3 to 6 days because of an unusually marked response in one, infection at the site of repair in the second, and because of persistent bleeding from the wound in the third. A fourth patient received 300 mgm. of dicumarol every 4 hours for 5 doses plus 50 mgm. of heparin every 4 hours for the same period. All anticoagulants were stopped when the mistake was discovered and 60 mgm. of synthetic vitamin K were given intravenously. No hemorrhagic difficulties ensued.

Despite the use of anticoagulants 3 patients developed thrombosis following resection of a traumatic aneurysm of the brachial artery with end to end suture in 2 and a vein graft in one. Scarring of the distal portion of the artery or imperfect suture is offered as a possible explanation for these failures. It is emphasized that there was no evidence of propagation of clot in any of the 3 cases.

In no case was any particular difficulty with hemostasis experienced even in the cases in which the prothrombin level had been altered beforehand by heparin or dicumarol. In several cases some later difficulty with bleeding was encountered. Hematomas developed in 3 cases in each of which the wound was reopened within from 2 hours to 30 days after operation and the clot evacuated. Slow persistent oozing from a surgical wound occurred in the fourth case. In one case dicumarol and heparin were stopped on the fourth day because the blood fossa was

great enough to necessitate vitamin K and a whole blood transfusion. The wound was explored and the capillary bleeding found to be stopped with closure of the incision.

In a second series of 256 cases in which the artery was simply ligated and divided no anticoagulants were used. In 2 of these postoperative thrombosis occurred and resulted in a nonfatal partial hemiplegia in the first case and gangrene of the foot necessitating amputation in the second. Infrequent as these disasters are, the authors speculate that they might be avoided by the routine use of anticoagulants.

Dicumarol is a dangerous drug if facilities for daily determinations of the prothrombin level are not available. Without them heparin can be used more safely. It is pointed out that heparin is apparently slightly more effective than dicumarol in preventing thrombosis following arterial trauma. In addition the critical period during which thrombosis is most likely to occur is immediately following operation. Hence the authors suggest that the most effective program may be the administration of heparin immediately preceding operation and for 5 or 6 days thereafter and combined with dicumarol for the following week or two. More extensive clinical trial is needed before a true evaluation of the procedure can be obtained.

The use of anticoagulants is not recommended in surgery of the abdominal, cranial, or thoracic cavities where postoperative bleeding may go unrecognized nor in surgery of the bones and joints for the same reason. While it is the authors' impression that heparin and dicumarol were of benefit in preventing arterial thrombosis, they state that they were not complete safeguards because an adequate and prolonged anticoagulant effect did not prevent thrombosis in two of their patients. The proficiency of the operator, the presence or absence of infection and the extent of local arterial injury are recognized as major factors influencing the outcome of the repair. Helpful as the anticoagulants may be, they will not assure success unless the focal damage is not great, and unless the surgical repair is perfectly performed.

SURGICAL TECHNIQUE

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Ascorbic Acid, Thiamine, Riboflavin and Nicotinic Acid in Relation to Acute Burns in Man
C. C. LUND, S. M. LEVY, R. W. GREEN, R. W. PARR, and Others. *Arch Surg* 947 55 557

This study is concerned with the alterations in the plasma concentration of ascorbic acid and in the urinary excretion of ascorbic acid, riboflavin and N-methylnicotinamide in patients with burns admitted to the Boston City Hospital, Boston, Massachusetts in 1944 and 1945.

The patients studied were cared for by members of the Burns Assignment of the Surgical Services of the Boston City Hospital. The dietary calculations were made by a research dietitian. All hematologic and routine chemical determinations were made by the methods previously reported from the Thorndike Memorial Laboratory. Determinations of plasma ascorbic acid were made in the Thorndike Memorial Laboratory by the method of Mindlin and Butler. The determinations of vitamin output were made in the Harvard Fatigue Laboratory. Both fasting and hourly excretion rates and the excretions after injections of test doses were determined. Low fasting hourly excretion rates of ascorbic acid, thiamine, riboflavin and N-methylnicotinamide together with low excretions of these substances after the injection of test doses were considered indicative of tissue unsaturation. Vitamin supplements were given orally in the form of ascorbic acid tablets and multi-vitamin capsules. Vitamins were given intravenously in the form of single or multiple vitamin preparations.

The percentage of body surface burned was estimated by the method of Lund and Browder. The depth of the burn was classified according to the method of Coover and Robb-Smith. Dressings in most instances were dry sterile pressure dressings applied usually without anesthesia. The dressings were changed at 1 to 2 week intervals. Grafting was done by the Padgett dermatome technique under cyclopropane anesthesia.

The cases studied are listed in the tables. There were 4 children with minor burns who were in excellent nutritional status on entry to the hospital and none had any complications before or after the burns. The fasting concentrations of plasma and vitamin C and the fasting hourly excretion rates of the various vitamins are listed in a table. In all instances these were within the expected normal range.

There were 3 children with severe burns. In one of these at the twenty-second hour after injury before any vitamin supplements were given, the fasting hourly excretion rates of ascorbic acid, thiamine, riboflavin and N-methylnicotinamide were normal. In 2 adults with minor burns no significant changes

from normal of the vitamins studied were noted. Only patients with some complicating factor such as pre-existing deficiency, low food intake, high fever, alcoholism, or serious infection will show important changes. The courses of such patients are given in detail.

The data presented demonstrate that after severe burns there are considerable alterations in the metabolism of ascorbic acid, thiamine, riboflavin, and nicotinamide. The extent of the abnormalities appears to parallel the extent of the burn. The evidence presented shows a low concentration of ascorbic acid in the plasma either with the patient fasting or after saturation tests and low urinary excretion of these vitamins in severe burns and in patients with complications. These changes were greatest in the early period following injury but continued in some cases far into the chronic stage. In this respect the alteration in vitamin metabolism parallels the changes in nitrogen metabolism which follows burns.

The authors conclude that large doses of ascorbic acid, thiamine, riboflavin, and nicotinamide are needed by severely burned patients and that some supplementation at a lower level is needed for many patients with burns of moderate extent. Similar conclusions had been reached in a study of patients with hemorrhagic shock, traumatic injuries, and infection. It is suggested that from 1 to 5 gm. of ascorbic acid, from 10 to 30 mgm. each of thiamine and riboflavin and from 150 to 250 mgm. of nicotinic acid be given daily to severely burned patients and that the doses may be needed for long periods. The diet should be high in carbohydrate and protein values and include ample quantities of yeast, crude liver extract, and vitamins A and D.

JOHN H. MONARDT, M.D.

The Treatment of Pulmonary Embolus by Stellate Block. WILLIAM E. BAUM and LAWRENCE A. RAFFEL. *Anesthesiology* 947 8 500.

The authors present a more practical aspect of blocking of the stellate ganglion to the syndrome of severe pulmonary embolus. The treatment of pulmonary embolus by stellate block is offered as an adjunct to the present therapy to relieve the acute episodes of this entity. Subsequent therapy of the patient is not in the scope of this paper.

The stellate ganglion is frequently formed by the fusion of the inferior cervical and the first thoracic sympathetic ganglion lying between the transverse process of the seventh cervical vertebra and the neck of the first rib on the medial side of the costocervical artery.

The technique of blocking the stellate ganglion varies, but whatever the approach, anterior or posterior, the surgeon must avoid (1) entering the pleura and causing pneumothorax, (2) injecting the anesthetic solution into a blood vessel, (3) injecting the

solution into the spinal fluid (4) anesthetizing the recurrent laryngeal nerve and (5) anesthetizing the phrenic nerve. Because of the last two complications a stellate block should not be done bilaterally at the same time.

A successful block results in a Horner's syndrome characterized by ptosis, miosis, anhidrosis, injection of the sclera, and increased temperature of the face, neck, arm, and chest wall of the injected side. The authors used the anterolateral approach and after producing a typical Horner's syndrome with 2 to 6 c.c. of a 1 per cent metycaine 1 c.c. of a long acting anesthetic in oil (novestoil) is injected for prolonged effect which persists for 2 to 6 hours and the effect of the block from 2 to 6 days or longer.

The authors report, in detail 2 cases in which stellate block was used with dramatic results.

In the first case, a stellate block was done two episodes of severe pulmonary embolus with dramatic and immediate relief of chest pain. dyspnea orthopnea, cyanosis, and a probable reversal of the shock syndrome. Pulmonary embolus was proven on each occasion by roentgenogram. The third embolus caused death. Necropsy proved the presence of old and recent emboli.

In the second case the patient was not in extremis but suffered severe dyspnea, chest pain and apprehension. A pulmonary embolus was proven by roentgenogram and after opiates had failed except for slight relief stellate block gave immediate and marked relief.

Surgical ligation of the pulmonary artery does not produce chest pain, dyspnea, orthopnea, cyanosis, shock, or death. The authors have listed the possible physiologic patterns in this mechanism.

The fact that pain impulses are transmitted by way of the sympathetic nervous system has been recently accepted by many as a definite entity. It is probable that the pulmonary embolus causes reflex vasospasm of the pulmonary vessels of not only the lung affected but of the vessels of the opposite lung as well. This spasm initiates painful impulses that are mediated by the sympathetic fibers innervating these vessels. These painful impulses plus vasospasm could account for the severe chest pain, dyspnea, orthopnea, chest splinting, and resultant shock seen in severe pulmonary embolic syndrome. In addition to reflex vascular spasm of the pulmonary vessels there may also be a regional sympathetic spasm of the coronary vessels as well regardless of the pulmonary vessels involved right or left. This may explain the bilateral chest pain that may occur and the frequent cardiac irregularities found in many cases.

The blocking of the stellate ganglion interrupts the painful irritation impulses arising from the sympathetic nerves innervating the pulmonary vessels. This apparently breaks up the vicious cycle—pulmonary spasm or coronary vascular spasm phenomena (or both)—by blocking the painful nerve impulses, as stated and permits vasodilation of the pulmonary vessels. The caliber of the bronchioles is ap-

parently unchanged. Repetition of the block is indicated if the cycle recurs.

No dogmatic conclusions are drawn by the authors but the use of stellate block is recommended in patients who have the syndrome of severe pulmonary embolus.

DAVID H. RYAN, M.D.

The Importance of Physiotherapy in Infections of the Hand (Le rôle de la physiothérapie dans les infections de la main) P. BAUWENS, *Bruxelles méd* 1947 27 2275

The infections of the hand have always constituted a difficult problem because of the serious consequences which may follow inadequate or incomplete treatment. The author pays tribute to Kanavel for having formulated the fundamental principles in the treatment of infections of the hand.

Adequate treatment rests on the trio consisting of surgery, chemotherapy and physiotherapy. Each factor is important and indispensable.

Classically a typical infection goes through four stages: inflammation, resolution, repair and functional restoration. These stages are not well delimited, but must, nevertheless, be recognized because the end results largely depend on the rapidity and success of dealing with them. Primarily all efforts are concentrated on arresting the infectious process. The surgeon must decide if chemotherapy is indicated, which agent and what avenue should be used. If surgery is indicated the surgeon must select the time for operation. The rules formulated by Kanavel and his followers should be followed as closely as possible. At the same time short wave treatment should be instituted. At first the whole limb is treated later on the intensity of the treatment is decreased and the treatment is concentrated at the site of infection. The treatment must be supplemented by absolute rest of the tissues directly or indirectly involved. The wrist as well as the hand and fingers must be immobilized in a plaster cast. It is of utmost importance to immobilize the hand in the position of function. The absolute rest reduces to a minimum the tendency of the infection to spread and also the amount of pain. One must, nevertheless, be on the alert for the formation of adhesions between various movable tissues. To prevent such occurrence it is necessary to mobilize the involved joints and tendons as much as pain will permit. It is advantageous to mobilize all the joints of the limb after each diathermy treatment.

After the infection has subsided and become simple inflammation chemotherapy is unnecessary but short wave treatment must be continued to aid in the process of resolution. The extent of immobilization of the affected part is also decreased.

During the stage of repair one must stimulate the proliferation of the tissues by using massive doses of ultraviolet rays. The author recommends a phlogotenic dose. According to Loofbourow and his colleagues, the cells destroyed by the ultraviolet rays produce hormones which have a stimulating effect on the proliferation of the underlying tissues.

To prevent loss of these water soluble hormones, a cod liver oil dressing is applied. Cod liver oil is used because it has an antiseptic effect due to its oxidizing capacity and not because of its vitamin content. When the treatment described is instituted early complications are rare and functional restoration is rapid. Delay in instituting rational treatment diminishes the possibility of obtaining a good functional result. Very often irreversible changes have taken place. The residual disability that may follow is usually the result of stiffness and adhesions. Massage, mobilization, and occupational therapy must sometimes be carried out for several months before maximum restoration of function is achieved.

GERARD GAGNON, M.D.

Tetanus in Kanawha Valley Treated in Charleston, West Virginia Hospitals. S. L. SCHAEFER. *West Virginia M. J.* 947 43 398

In the present article the author reports 33 cases of tetanus which occurred in Kanawha Valley. The patients were treated in Charleston, West Virginia, hospitals. He has based his studies on the 20 patients for whom records were available. Of these 20 7 died a mortality of 35 per cent. Two unusual etiologic agents were otitis media and snake bite. In 1 case tetanus developed 345 days after injury 5 days after open reduction of a compound fracture which had been sustained at the time of the original injury and had failed to unite. Incubation periods for the 20 cases varied from 3 to 345 days, but the length of the incubation did not appear to influence the outcome.

The discussion of pathology symptomatology, and treatment restates sound surgical principles and offers some new therapeutic suggestions. The mechanism of formation of secondary toxic substance resistant to antitoxin, is discussed. The value of immunization with toxoid is affirmed and adequate early wound toilet is emphasized.

Since 3 of the patients in this series had definitely had 1 500 units of antitoxin the author believes that the routine prophylactic dose should be 3 000 units. For initial treatment of the established disease he recommends 80,000 to 100,000 units of antitoxin of which 40 000 to 60,000 units should be given intravenously and the balance intramuscularly.

BENJAMIN F. LOUGHBURY, M.D.

ANESTHESIA

The Technique of Pain Control. BERNARD D. JUDOVICH and WILLIAM B. TER. *Surg. Clin. N. America* 947 7 343.

The authors approach to the technique of somatic pain control hinges largely upon the pattern of tenderness which is associated with the pain, rather than on focusing attention only upon the area of the patient's complaint. Somatic pain is divided into three types (1) local (2) transmitted and (3) reflex.

Classification of the patient's complaint determines the areas to which study and therapy are to be di-

rected. In the local type of pain, the studies and therapy are applied to the area of complaint. In the transmitted type, attention is directed to the spine and its surrounding areas if segmental nerve tenderness is present. In the reflex type of pain, the segments are identified and all skeletal structures receiving nerve supply from this level are carefully examined for a local lesion which produces the radiation.

Of greatest value in controlling pain are the methods which interrupt the afferent pathways. Local infiltration and paravertebral nerve block have proved to be the most effective of all the conservative procedures.

The scalenus anticus syndrome is one of the most common causes of pain in the shoulder girdle and upper extremity. Failure to distinguish between the primary and secondary types, and their causes, and ignoring brachial plexus and sympathetic anesthesia following diagnostic procaine infiltration are the main reasons patients still complain of their original pain after the anterior scalenus muscle has been transected. In the secondary scalenus syndrome, the muscle should not be transected. Many conditions may simulate the anterior scalenus syndrome. None is relieved by a diagnostic infiltration of the muscle.

In any patient with chronic pain and tenderness of the walls of the chest or abdomen a careful examination of the back should be made. If segmental neuralgia is present, the treatment of choice for rapidity of results and duration of relief is paravertebral nerve block.

Lesions causing reflex pain along the course of the sciatic nerve do so because of irritation of somatic structures supplied by branches of the sciatic distribution. Infiltration of the sciatic nerve has been of definite value in the control of pain.

In acute cases of herpes zoster good results are obtained from therapeutic paravertebral nerve block with procaine and ammonium sulfate. In the chronic cases little or no relief of pain was obtained.

The use of intraspinal alcohol is to be reserved for incurable cases and for patients who have severe pain which cannot be alleviated by other forms of therapy. Since 1939, the authors have been using ammonium salt solutions intraspinally and for nerve block. The action of the ammonium ion is that of depression of the C fiber potentials. The ammonium salts are to be used only for pain of this transmitted type which as mentioned, is associated with nerve pattern tenderness.

The intravenous administration of procaine appears to be of definite value in the relief of pain, particularly in cases of trauma or when sympathetic release is desired. The relief of pain takes place by transudation of procaine in areas where capillary permeability is increased in connection with injury inflammation, or edema. Sensitization to the drug is particularly apt to develop in patients with chronic urticaria.

Failures should be investigated from several angles. If the segmental tenderness disappears and the pain

perists it may be caused by (1) a lesion proximal to the point of infiltration, (2) a local lesion which is overlapped by a zone of segmental neuralgia, (3) a visceral lesion which may coexist with the segmental neuralgia and (4) medicolegal complications in which the patient refuses to admit relief of pain.

Among these patients there are undoubtedly some who reflect psychosomatic situations. However applying the term psychosomatic to patients only because no disease can be found is an implication that we have knowledge of all the causes of pain. This is far from the truth.

MARY FRANCES POE, M.D.

Anesthetic Mortality in Intrathoracic Surgery H. LIVINGSTON, G. LIGHT J. CORO and R. ENOKL. *Arch. Surg.* 1947 55 545

The need for intrathoracic operations arises frequently in the management of neoplastic, inflammatory and congenital lesions of the organs within the thorax. These procedures are accompanied by many unusual surgical and anesthetic hazards. Many of the patients are grave risks with manifestations of serious alterations of their cardiorespiratory mechanisms and nutritional state.

In a series of 688 intrathoracic operations the outcome and the relationship of the deaths to the anesthetic management were investigated. Fifty nine or 8.5 per cent of the patients died. The greatest number of deaths occurred 1 to 3 days postoperatively. Death followed a surgical accident in 1 case. Twenty three and seven tenths per cent of the deaths were due to the operation and the disease and the same percentage were due to the disease alone. None of the deaths were due to the anesthetic alone.

Deaths during or following intrathoracic surgery can be minimized by judicious care. Preoperative preparation involves the administration of adequate fluids, plasma and blood transfusions, removal of fluid or secretions from the esophagus, stomach or respiratory tract, and other general measures to improve the condition of the patient.

The maintenance of the anesthetic state is but a small part of the management of anesthesia in intrathoracic procedures. Adequate pulmonary ventilation at all times is of utmost importance. Undue alteration in the cardiorespiratory mechanism must be prevented. The two most important details are the prevention of anoxia and the removal of foreign material from the trachea and bronchi. It is not considered imperative to introduce an endotracheal catheter if a clear airway is evident. Oxygen administration with adequate inhalation pressure is most important. It is necessary to replace promptly all blood lost during the surgical procedure. Routine bronchoscopic aspiration of mucus and blood from the tracheobronchial tree is indicated before the patient leaves the operating room.

Proper postoperative management includes oxygen therapy instituted immediately after operation, the maintenance of a patent airway and prompt aspiration of secretions from the air passages. Continuous suction drainage is applied to a stab wound

drain of the pleural cavity except after pneumonectomy. Adequate water and mineral balance must be maintained. Transfusions of blood and plasma should be repeated when indicated.

MARY FRANCES POE, M.D.

Nupercaine in Dilutions Greater than 1:1500 for Spinal Anesthesia. A. J. FISHER and R. J. WHIT. *ACR. Anesthesiology* 1947 8 584.

The effectiveness of nupercaine as an anesthetic drug has led to the clinical use of this agent in concentrations less than the 1:1500 dilution ordinarily recommended for spinal anesthesia. In order to evaluate the clinical effects of nupercaine in greater dilution, concentrations varying from 1:2000 to 1:10,000 were used in 134 cases of which all but 61 required intra-abdominal operations. The nupercaine solutions were made definitely hypertonic by the use of dextrose. Because sensory anesthesia was usually incomplete, light first plane cyclopropane anesthesia was routinely administered as a supplement.

It appears that the duration of the spinal block is not materially affected by the dilution of nupercaine. Likewise, the degree of relaxation obtained from a given dose of drug did not seem to be influenced by the various dilutions used. There is no evidence that the dilution of nupercaine has any effect upon either the incidence or the severity of circulatory reactions. It appears likely that the size of the dose rather than the dilution is the primary factor to be considered in attempting to minimize circulatory disturbances under nupercaine spinal anesthesia.

It is concluded that there is little or no advantage in using concentrations of nupercaine less than those ordinarily recommended for spinal anesthesia.

SURGICAL INSTRUMENTS AND APPARATUS

Cotton as a Suture Material in Surgery (Il cotone come materiale di sutura in chirurgia) GIOVANNI D'ENRICO. *Gior. ital. chir.* 1947 3 550.

The author reviews the literature and summarizes the advantages of cotton as advanced by Ginkovski, Meade, Ochsner, Thorek and Foss. He also mentions the reports of D'Inguanni (1945) and Derbyshire (1947) who claim that while cotton is an excellent suture material it is not without risk and has well defined limitations.

The author challenges the popular belief that in sections are less common with the use of cotton. He believes that they are as common as with other non absorbable materials.

In the Naples Surgical Clinic of Torraca, cotton was first used in October 1946. Up to June 15 1947 about 500 operations in which cotton was used for suture were performed. In exceptional cases the material was used alone, usually it was used with catgut but in a few cases it was used with silk or linen.

It is noted that the first surgeons to use cotton adhered to the teachings of Halstead on the use of silk and recommended that not both absorbable and non

absorbable material be used. It is known that these precepts no longer hold with regard to silk as practice has demonstrated that continuous sutures simple ligatures, and the association of silk and catgut sutures do not expose the patient to particular dangers.

In the author's clinic, cotton is used almost always for ligatures and in certain cases for seroserosal and parietal sutures. Number 60 (American nomenclature) is used for ligatures of small vessels and seroserosal sutures. Number 24 is used for larger vessels and the peritonea.

Three complications were encountered. One was wound dehiscence on the fifth day following a gastric resection complicated by postoperative bronchopneumonia. The wound had been closed with cotton. This was successfully repaired with silk and catgut. The second was wound infection in a bilateral Bassini repair of inguinal hernia. Drainage ceased in 3 months after four sutures were expelled. The third occurred in a 43 year old woman who was operated on for the third time when a cholecystectomy was performed. Bronchopneumonia and phlebitis followed. On the tenth day a moderate dehiscence of the wound was noted. For 4 months a large number of sutures were expelled. This was followed by a tumefaction in the epigastric region which was resected and found to be made up of two hard masses of connective tissue one attached to the gall bladder bed and the other attached to the transverse colon.

The first complications were not considered to be due to the cotton especially as they could have occurred with any type of suture material. The third

complication was considered to be an aspecific reaction to a foreign body.

Experiments were performed on 10 rabbits with scrupulous aseptic technique. Two dorsal incisions were made in each animal and the muscles in the paravertebral space were sutured with catgut, silk, linen, and cotton. Numbers 60 and 24 cotton were used and corresponding sizes in the other materials. Four sutures were used in each incision, one of each material and of corresponding size. The catgut used was sterilized with dry iodine and the sizes were 000 and 0. All wounds healed per primam.

The animals were sacrificed successively from the second to the fiftieth day. The sutures together with the adjacent musculoaponeurotic tissue were removed and examined macroscopically and microscopically.

The results are summarized as follows:

All sutures, both absorbable and nonabsorbable, held well (until catgut began to show signs of absorption). The catgut sutures held long enough to assure healing of the tissues.

The decomposition and absorption of catgut caused a larger exudative and leucocytic response. The author did not find cotton to show less response than silk or linen and therefore disagrees with the opinions of Meade and Oschner and Thorak on this subject. From his point of view there is no reason to prefer cotton to silk or linen.

The use of cotton does not eliminate the danger of wound dehiscence or fistula in case of infection. The author finds no particular advantage or disadvantage in using cotton instead of silk or linen.

LESLIE J. FROMMELT, M.D.

vity could not be definitely determined during the period of observation and 4 patients (50 per cent) were found to have healed old coccidioidomycosis with stable pulmonary lesions. The cause of 1 patient's pulmonary infiltration could not be ascertained.

The importance of continued observation, repeated sputum and gastric examinations for acid-fast bacilli, serial chest roentgenograms and weekly determination of the sedimentation rates as aids in determining the activity of pulmonary lesions, is stressed.

FRANK L. HUMET, M.D.

The Differentiation of Mediastinal Tumor and Aneurysm by Angiocardiography MARCY L. SUTEMAN *Am. J. Roentg.* 947 58 584.

Prior to visualization of the heart and great vessels by rapid intravenous injection with contrast media, the differentiation of mediastinal tumor and aneurysm was by inference; however, in view of the rapid advances which have been made in thoracic surgery more precise roentgenographic diagnoses are now required.

The author presents 6 cases to illustrate the scope of angiocardiography in the study of mediastinal masses.

These include (1) dermoid cyst of the anterior mediastinum (2) aneurysm of the descending aorta, (3) poststenotic aneurysmal dilatation in coarctation of the aorta, (4) dilatation of the pulmonary artery, (5) dilated aneurysm of the ascending aorta, and (6) bilateral thymoma.

Occasionally a large aneurysm will not fill with the opaque media due either to the presence of a large clot or a very small neck. Frequently however there are abnormalities, or dilatation of the aorta or pulmonary artery which suggest the diagnosis. Usually tumors do not affect the heart or great vessels except by displacement. Rarely a fibrous tumor may produce a traction aneurysm or malignant infiltration may produce irregular constriction or even occlusion.

R. B. LEWIS, M.D.

Abdominal Venography PEDRO L. FARIAS, *Am. J. Roentg.* 947 53 590

A relatively simple technique is used by the author in an effort to visualize the inferior vena cava and iliac veins. Under local anesthesia, a small incision is made in the middle third of the thigh; the long saphenous vein is exposed and a small trocar is inserted. Usually a tourniquet is placed at the groin level but this is released before the contrast is injected. Thirty cubic centimeters of media are injected rapidly and a 14 by 17 inch film is taken. As rapidly as possible the remainder of the dye (10 c.c.) is injected and the second film is exposed.

Normal venography reveals the femoral, external and common iliac veins and the inferior vena cava; the caliber of the vessel increases as it ascends the lumbar vertebrae, with a compression in the epigastrium. An inflated balloon can be effectively used to visualize the hepatic and renal veins.

Indications for abdominal venography are

- 1 Possible obstruction or thrombosis of the inferior vena cava.
- 2 Abdominal tumors.
- 3 Liver pathology possibly resulting in portal hypertension and necessitating a portal vein and vena cava anastomosis.

MAURICE D. SACCH, M.D.

Abdominal Arteriography; Technique and Diagnostic Application FREDERICK B. WAGNER, JR., ALBION H. PRICE, and PAUL C. SWANSON *Am. J. Roentg.* 947 58 59

Visualization of the abdominal aorta is not an established procedure because of its hazards and complicated technique. The authors describe a simple method which has been used as a diagnostic adjunct with no sequelae in 26 patients.

Preliminary preparation consists of an enema in the morning, no food, and a morphine and atropine hypodermic 45 minutes before the procedure.

A team consisting of a surgeon, two anesthetists, and a roentgenologist is necessary.

The roentgen technical factors are 70-85 kv. 300 ma. 35 second, Potter Bucky diaphragm 30 inch target film distance, fast film, and par speed screens. It is advisable to take a preliminary film to check for proper cleansing, the desired anatomy region, and the correctness of the exposure factors. The technician is ready to take the roentgenogram when the signal is given.

Before the aortic puncture, the patient is anesthetized with a 2 1/2 per cent pentothal sodium solution. The second anesthetist administers oxygen. Emergency drugs such as epinephrine and coramine should be available if necessary.

A number 18 gauge malleable needle is used for the aortic puncture. To this are attached 2 feet of rubber tubing with a Luer Lok adapter and 10 c.c. syringe. Extra openings along the side of the needle near the tip will decrease resistance to the injection. With strict surgical technique on the x-ray table 10 c.c. of an 80 per cent sodium iodide solution are injected into the aorta. For an aortic puncture at the level of the twelfth dorsal vertebra, the skin is pierced below the left twelfth rib 4 fingers breadth from the spinous process. The needle is directed anteriorly medially and cephalically toward the body of T12 until bone is encountered. It is then withdrawn a cm. and inserted laterally into the aorta. A sharp snapping sensation is felt when the aorta is entered. The renal artery is best visualized by entering the aorta at L-1 and the iliac vessels at L-2.

Before dye is injected, a preliminary precaution of alternate saline injection and blood withdrawal should be tried several times to assure the operator that the needle is in correct position. Ten cubic centimeters of sodium iodide are injected at the rate of 2 c.c. per second. As the final 1 or 2 c.c. of dye are leaving the needle, the signal is given for the roentgen exposure and the needle is then withdrawn.

The patient recovers from the anesthesia in from 5 to 10 minutes. A liter of 5 per cent glucose is ad-

ministered via the intravenous anesthesia needle which is left in place. No case of iodism has been observed.

This procedure is a valuable diagnostic aid in aortic aneurysms, occlusions, peripheral vascular disease, abdominal tumors, hypertension, and hydrocephalus associated with aberrant vessels. However, the examination should be done only by trained personnel and only after the usual studies have failed to yield enough information for a diagnosis.

MAURICE D. SACHS, M.D.

Röntgen Visualization of the Inferior Vena Cava
BERNARD J. O'LOUGHLIN *Am J Roentg* 1947 58 617

The author presents a method for the contrast roentgen visualization of the inferior vena cava which he believes is simple and safe. The method consists of injecting 35 per cent diodrast into the femoral vein and visualizing the external and common iliac veins and the inferior vena cava on films. No serious or ill effects have occurred in any of the 50 patients injected.

FRANK L. HUSSEY, M.D.

Röntgen Findings in Duodenal and Primary Pancreatic Malignant Lesions. J. R. KUNK and G. J. CULVER. *Am J Roentg* 1947 58 435

The authors discuss the roentgenologic aspects of primary duodenal and pancreatic malignant lesions and present 3 cases to illustrate the lesions. Carcinoma of the duodenum is a rare condition, however, it must be borne in mind when considering lesions of the upper gastrointestinal tract.

In the suprapapillary portion of the duodenum the lesion is usually a constricting one narrowing the lumen, and infiltrating and eroding the mucosa. This type of lesion is usually a scirrhous adenocarcinoma. In this type the most common symptom is pain and the stool is frequently positive for blood. The roentgenoscopic finding after the ingestion of a barium meal is a very small protuberance jutting into the lumen with the mucosa destroyed over the area. There is no associated spasm or tenderness such as one finds in inflammatory lesions. Spot roentgenograms are of value to demonstrate the mucosal detail in this and other lesions of the duodenum.

In the penampullary portion, the lesion may be a constricting adenocarcinoma as previously described producing the same signs and symptoms. In addition this lesion if arising near the papilla of Vater may very early infiltrate the papilla and cause a blockage of the flow of bile into the duodenum. Jaundice and light colored stools may occur.

Papillary adenocarcinoma in this region causes constriction after the mucosa and submucosa become infiltrated. The stool is often positive for occult blood. Carcinomas in this region produce the same roentgenographic findings as described, however, the filling defect may be greater. This lesion cannot be differentiated from a lesion of the ampulla of Vater.

Carcinoma of the infrapapillary portion of the duodenum is the least common of these lesions. This lesion usually occurs near the duodenojejunal junction and is most often an infiltrating constricting adenocarcinoma. It is usually scirrhous in type and metastasizes early. Symptoms appear later and are usually pain and occult blood in the stools. The earliest roentgenological finding is narrowing of the lumen. Destruction and distortion of the mucosal folds and a loss of the distensibility and pliability of the wall also occurs.

Carcinoma of the ampulla of Vater obstructs the common bile duct early. Jaundice and light colored stools are early symptoms. Occult blood in the stool and secondary anemia occur. There is a tendency toward early metastasis. Annular constriction may be produced by lymphatic extension. Following ingestion of a barium meal a small filling defect protruding from the posteromedial or medial wall of the second portion of the duodenum is seen. The mucosa may be eroded or distorted.

Invasion of the duodenal wall by carcinoma of the head of the pancreas may resemble carcinoma of the duodenum. Painless and progressive jaundice are the cardinal symptoms. If the lesion erodes the duodenal wall or duodenal mucosa the stools may be positive for occult blood. An increase in the duodenal movement does not occur in early lesions. A primary carcinoma of the bile duct with duodenal extension may resemble a primary carcinoma of the duodenum. It produces signs of common duct obstruction early. The other symptoms are distended gall bladder pain and abdominal distress. If the lesion erodes the duodenum at the site where the duct passes under the first portion of the duodenum the duodenal mucosa may become eroded with roentgenographic findings similar to those of a primary carcinoma of the duodenum.

Aberrant pancreatic tissue tumors in the wall of the duodenum may produce stenosing lesions without any change in the mucosal pattern. They are differentiated from the primary carcinoma lesions by this factor. The importance of correct diagnosis is to bring the patient to surgery early while the lesion is still localized.

FRANK L. HUSSEY, M.D.

Newer Methods of Pneumarthrography of the Knee with an Evaluation of the Procedure in 315 Operative Cases. ISAACORE MESSCHAN and W. H. MCGAW. *Radiology* 1947 49 675.

The authors analyze 315 operative cases in which pneumarthrography of the knee was done. Oxygen is recommended for pneumarthrography because it is quickly absorbed. From 80 to 120 c.c. of oxygen are injected under gentle pressure into the joint space after the usual antiseptic preparation of the knee. The findings in normal and abnormal pneumarthrograms are presented in detail. The pneumarthrogram is of special value in the diagnosis of abnormal menisci, fat pads, and bursae. These cases account for over two-thirds of the major lesions in internal derangement of the knee joint.

In other causes of internal derangement of the knee, the plain radiograms are usually of equal value for diagnosis. It is not necessary to use pneumarthrograms for the diagnosis of osteochondritis dissecans or chondrosis of the patella. Popliteal bursae occurred in 13.5 per cent of the present series of cases.

The pneumarthrogram was found to be accurate in 81.6 per cent of the cases. It is estimated that the clinical examination alone is accurate in about 70 per cent, thus the pneumarthrogram has achieved a greater accuracy than the clinical examination. Moreover, with the pneumarthrogram the type and completeness of the lesion can be predicted more accurately. With the combined use of clinical examination and pneumarthrograms accuracy can probably be achieved in 90 per cent of the cases.

FRANK L. HUMBY M.D.

Carcinoma of the Bronchus with Especial Reference to Its Treatment by Radiotherapy. L. M. SHORVOG. *Bull J Radiol* 1947 20 443

The author analyzes a series of 213 cases of carcinoma of the bronchus seen in Mount Vernon during the years from 1942 to 1946. Of the patients in this group 75 were too ill and their disease was too advanced to permit radiation therapy. Palliative treatment was given to 23, 2 of whom had had a recurrence after pneumonectomy. Four patients were given postoperative deep x-ray therapy, 3 after pneumonectomy and 1 after lobectomy and 111 received radical treatment.

The results of radiation therapy are evaluated under three headings: possibility of cure, prolongation of life and relief of symptoms. The possibility of cure is remote. Not one radically treated patient has survived longer than three years after completion of the treatment. The prolongation of life is a difficult thing to evaluate satisfactorily because it is difficult to decide when the malignant process actually started. Statistically the treated patients survived longer than the untreated ones.

Complete or marked relief of such symptoms as pain, cough, dyspnea, and superior vena caval obstruction is often obtained by radiation therapy. Some patients enjoyed a period of comparative normality.

FRANK L. HUMBY M.D.

Röntgen Therapy in Uterine Fibromyomas without Ovarian Sterilization. GEORGE E. FRANKEL. *Am J Roentg* 1947 58-798.

The author presents a report of 4 cases of uterine fibroids of the interstitial type which were treated by roentgen therapy following which normal pregnancies occurred. The ovarian regions were protected by lead and in none of the 4 patients was menstruation interrupted. In 2 of these, treatment was followed by a total of 6 pregnancies. All of the children were normally formed. The first woman had 4 healthy children, 3 of whom are living today. The second patient had 3 children of premature birth, which was believed to be due to accidental causes not related to the irradiation; one child is well at 7 years of age.

The third patient has never become pregnant but has menstruated regularly. The fourth patient received some treatments over the ovaries and had an interruption of menstruation for a period of 6 months. She then became pregnant at the age of 32 years, and again at 33; the child is now a healthy girl, 20 years of age.

The author believes that roentgen rays have a direct action on fibromyomas and cause a disappearance of the tumor without affecting the ovaries, and that healthy children may be born after treatment for uterine fibromyomas. FRANK L. HUMBY M.D.

Further Observations with Intravaginal Röntgen Therapy of Cancer of the Female Pelvis. W. WALTER WASSON and ROY GREENING. *Radiology* 1947 49-453

The authors discuss some of the failures of roentgen therapy of cancer of the female pelvis and offer certain procedures with the hope of better end-results.

It can be said that the ultimate goal in treating carcinoma of the cervix by irradiation is to deliver a dose of uniform distribution throughout the pelvis and of sufficient intensity to destroy the cancer cells.

After a description of the anatomy of the pelvis and a discussion of the merits of the various diagnostic methods, the authors deal in particular with the type of radiation therapy consisting of a combination of external and intravaginal roentgen therapy.

The external roentgen therapy is carried out with either 300 kv or 400 kv. In the average case, a dose of 5,500 roentgens may be delivered through 4 or 5 portals into the structures of the birth canal over a period of a few weeks without approaching the limit of skin tolerance. Since 4,000 roentgens within the tumor cells is probably the optimal amount, there remain 1,500 roentgens to be given either by intravaginal roentgen therapy or by intracavitary radium. According to the authors, one of the advantages of intravaginal roentgen therapy is that it offers a greater flexibility to administer this remaining dose of 1,500 roentgens.

The irradiation is carried out through cones of various sizes suited to fit the vaginal canal. Multiple portals are used for crossfiring directed at the cervix and the surrounding structures or only at the cervix and broad ligaments. Either 140 kv or 300 kv may be used. Care must be taken to avoid overlapping. If a cone of 3.3 cm in diameter is employed, a satisfactory irradiation of the pelvis in the transverse diameter is possible provided three areas are given in the transverse diameter or the pelvis can be covered in the anteroposterior diameter if three areas are given in this diameter. With the use of smaller cones, unexposed spaces will remain between the treated areas. The sum of the diameters of the areas treated must equal the diameter of the birth canal.

If a uniform irradiation of the cross section of the pelvis cannot be accomplished by the intravaginal roentgen therapy supplementary radium treatment

may prove necessary. This applies especially to carcinomas of stages II, III and IV. Radium should also be used in carcinomas of the early stage when there is a purulent discharge present.

The authors have tried larger tumor doses than 4,000 roentgens per series of treatments but some delayed reactions were encountered about the cervix and vaginal vault. It is recommended that if a tumor dose of 5,000 roentgens is given in one series it should not be repeated at least in that same amount.

Intravaginal roentgen therapy is also of value in residual tumors following operations upon the uterus and ovaries or about the cecum, bladder and rectum. It is possible to crossfire the tumor in such instances through the vagina and by external irradiation.

The Biologic Effects of Fife Radiations. P. S. HENSHAW, E. F. RILEY and G. E. STAPLETON. *Radiology* 1947 49 349

The authors report results of experiments carried out at the Clinton Laboratories, Oak Ridge, Tennessee, as part of the extensive biological program of the Manhattan Project.

Experiments were carried out with several strains of mice to determine the late effects of periodic and single exposures of fast neutrons, slow neutrons and gamma rays (penetrating radiations). Similar experiments were carried out with beta rays, the absorption of which was limited almost exclusively to the skin.

In general, the late effects resulting from exposure to penetrating radiations, irrespective of the method of exposure, consisted of generalized atrophy and neoplasia of hemopoietic organs. Both effects were attended by a shortened life span, loss of weight

some increase of tumor incidence in organs other than hemopoietic, a modified blood picture and a changed pathology and histology all of which served as criteria of irradiation effects. It was plain that the chain of events between treatment and death did not always follow the same pathway even with identical treatments and animals of uniform type.

Survival time, which was one of the most sensitive responses, showed effects following daily exposures in the range of 0.1 neutron of fast neutrons and 1 roentgen of gamma rays. Threshold responses of the peripheral blood were often less sensitive than threshold survival responses in C57 mice. Slight differences were observed in different strains. No fundamental differences were observed in the responses of the different sexes.

The r/n ratio of gamma rays to fast neutrons for the different effects varied roughly from 8 to 1 to 35 to 1 for the conditions and methods used. The degree of acute damage (as measured by survival after single massive dose exposures) varies not only with dose but also with the intensity of irradiation, a 10-fold increase in exposure time for gamma ray treatment reduced the effects observed for a given dose to about 70 per cent. Thus the degree of biologic effect varies not only with the dose but also with the density of ionization produced. The incidence of lymphoma was increased from 15 per cent in controls to over 60 per cent following single exposures of from 500 to 700 roentgens of gamma rays. Lung tumor incidence was increased little if any.

Sublethal doses of beta rays produced skin lesions especially malignant types in rats and mice. Following doses of from 4,000 to 5,000 roentgen equivalent physical animals that ordinarily have no skin lesions showed skin carcinomas. It is significant that hemopoietic tissue tumors were obtained with penetrating radiation and skin tumors with surface absorbed radiations.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Amino Acid Utilization. PAUL R. CANNON *J Am Med Ass* 1947 35 943.

Rats, previously prepared by a diet low in protein but adequate in calories, vitamins and minerals, were used to test the speed of tissue synthesis under varying nutritional conditions. Tissue synthesis proceeded in direct relation to calories when repletion diets adequate in protein content but with varying caloric levels were fed. When the caloric content of the standard repletion diet was below 70 per cent recovery of weight was poor when it was above this level the addition of extra calories had but slight additive effect. In other words, tissue synthesis requires enough calories to facilitate the conversion of amino acids into tissue protein but above a certain level additional calories are superfluous.

Calories, per se do not build tissues. They are built from dietary proteins by conversion of their amino acids. Protein depleted rats which were fed a series of standard high caloric repletion rations each containing a decreasing amount of high quality protein regained their weight and appetite in direct relation to the protein content. These experiments demonstrate that for effective recovery of lost weight or for the regeneration of plasma protein and hemoglobin, high quality protein and calories are mutually indispensable, and a deficiency of either one may constitute a limiting factor which hampers effective convalescence. Vitamins and minerals must also be restored as well as the enzyme systems which in the debilitated patient may be severely impaired.

It is suggested that tissue protein synthesis is rapid and "all or none" in character when once it starts. One might presume that the synthesizing mechanisms may operate effectively only under the following general conditions: they must have available all essential dietary elements; the synthesizing cells must be uninjured if they are to obtain the energy necessary for the task of synthesis; conditions must be such that these cells, once the synthesis starts, can do a perfect job.

That presumably there is an overall proportional relationship between the various amino acids is suggested by the work of Beach and of Bailey: thus, for example, for every molecule of tryptophane required for the synthesis of muscle protein a certain specific number of molecules of the other essential amino acids are required. Examination of the high quality proteins which promote good tissue synthesis reveals that they contain such an assortment of essential amino acids, and that in the process of tissue synthesis, they may be made available to the synthesizing mechanism in proportional amounts. This relationship becomes of extreme importance because of accumulating evidence of the lack in the tissues of

reserves of individual essential amino acids. The phenomena of negative nitrogen balance appear so quickly with the removal of a single essential amino acid from the diet and disappear with equal speed when it is restored that it is difficult to postulate the ready availability of any essential amino acid reserves. In the absence of a single essential amino acid tissue synthesis stops; the remaining essential amino acids are presumably converted into glucose or are deaminated and excreted, and the synthesizing mechanism, rather than fabricating imperfect tissue protein, waits until a complete assortment is again available. Elman's work with the intravenous injection of acid hydrolysate of casein supplemented with tryptophane immediately and 6 hours later which revealed nitrogen retention in the first instance and lack of it in the second, is cited in support of the author's idea.

Two standard rations containing differing sets of essential amino acids when fed to rats at a hour intervals revealed that the animals could not eat the two rations quickly enough in relation to one another to enable the second group of essential amino acids to combine with the first group in order to accomplish tissue synthesis. Therefore, it is suggested that all the essential amino acids must be present at approximately the same time, for the individual amino acids from an incomplete ration cannot be stored in the liver or elsewhere for much longer than an hour. Thus the utilization of amino acids in tissue fabrication is extremely rapid and for optimal utilization each meal should be well balanced as to content and proportions of essential amino acids. The poorer nutritive value of vegetable proteins—soy beans, for example—may well be explained on the basis of their unequal rates of enzymic digestion and the correspondingly unequal rates of absorption of amino acids.

Protein hydrolysates and protein concentrates, assuming that these products contain all the essential amino acids in adequate amounts and proportions are seen to possess certain theoretic advantages in surgical practice, although it must be remembered that their complete utilization still depends on the efficiency of the synthesizing mechanism.

ALLAN D. CALLOW M.D.

Metabolic Disturbances after Injury. J. BRATHEN. *Brit Med J* 1947 3 3.

Only within the last 20 years has the metabolism of injured persons been studied accurately. One of the most significant findings concerns nitrogen metabolism. Following injury the average well nourished individual excretes an increased amount of nitrogen in the urine. This output increases to reach a peak at the end of the first week. Then it gradually declines to a normal level, attained in less severe injuries by the end of 2 or 3 weeks. The output may

decline still further but it rises again to a normal level by the end of 2 or 3 months. Thus it can be seen that there are catabolic and anabolic phases in the cycle of nitrogen metabolism evoked by an injury. The initial catabolic phase may be lessened but cannot be abolished by high protein diets given in the first week or 10 days after injury. Continuation of such diets will effect a positive nitrogen balance during the latter half of the period of high urinary nitrogen loss. The magnitude of the urinary loss is dependent on the individual's state of nutrition and on the severity of the injury. Poorly nourished patients have only a slight metabolic response or none at all as measured by urinary nitrogen loss. Even given high-protein diets such patients do not lose appreciable amounts of nitrogen in the urine. The fact that they do not catabolize the added protein suggests that the mechanism for the catabolic response has been inhibited. A severe injury such as occurred in the case of burns of hands and arms quoted by the author may have a marked negative nitrogen balance for a long time in this case, the loss was 216 gm. over a period of 47 days.

The mechanisms involved in these metabolic disturbances are not known. A small part of the negative nitrogen balance may be ascribed to the effects of immobilization as normal individuals kept in bed for weeks show a negative balance. However this is a relatively minor factor. The source of the nitrogen loss seems to be dispensable nitrogen which is "stored" in the body cells; this can be used as it is needed without loss of cell viability. Some observers have calculated that at least 15 per cent of the body nitrogen is in the dispensable category. It appears that when this nitrogen has been lost some factor operates to check the loss. Thus after injury in poorly nourished individuals there is no catabolic phase of nitrogen metabolism because this protective mechanism is already at work. In well nourished individuals the urine contains large amounts of corticosteroid material a few days after injury presumably derived from the adrenal cortex. It is thought that this inhibits the synthesis of amino acids into proteins. Consequently if these acids are not utilized by the body but are deaminated by the liver and in part built into liver glycogen their nitrogenous fraction is transformed into urea and excreted. In debilitated patients the urine does not contain these large amounts of corticosteroid material. Cuthbertson has advanced an interesting hypothesis that the increased nitrogen output may result from the breakdown of protein molecules in the body's attempt to supply some component amino acid of the protein molecules which is essential to the process of repair. If this one amino acid makes up 3 per cent of the protein molecule the remaining 97 per cent would have to be metabolized.

After injury there is greater need for vitamin C. Some of this may result from an increased utilization of ascorbic acid by the adrenal cortex. Some of the increased need may be due to an increased requirement in the liver where ascorbic acid is known to

augment the enzyme arginase which appears to be concerned in urea production. Some of the increased demand is known to be due to the requirements of the injured tissue for repair.

Excretion of calcium after injury is greatly increased in the urine and moderately increased in the feces. Following fractures the increased output of calcium may reach a dangerous level since insoluble calcium phosphate may be precipitated in the urinary tract to form calculi.

Effects of Tetraethyl Ammonium Chloride on a Mixed Type of Hypersensitive Carotid Sinus Syndrome ROBERT D. TAYLOR, LEX C. UNDERWOOD and IRVING H. PAGE. *J. Lab. Clin. Med.*, 1947 32: 1491

A 59-year-old man who had a hypersensitive carotid sinus syndrome was observed. Stimulation of the sinuses by pressure caused bradycardia, reduction of the blood pressure, giddiness and syncope. The bradycardia was presumably due to increased vagal tone and the fall of the arterial pressure to vasodilatation of sympathetic origin. Atropine sulfate by its ability to inhibit parasympathetic activity blocked the vagal component but had no effect upon the sympathetic component. Tetraethyl ammonium chloride which paralyzes both parasympathetic and sympathetic ganglia prevented both responses.

The inhibition of the sympathetic nervous system by tetraethyl ammonium although more complete than that of atropine is of brief duration; it is not recommended for the treatment of the hypersensitive carotid sinus syndrome of this type.

WALTER H. NADLER, M.D.

Pathologic Anatomy in 2 Cases of Myasthenia Gravis (Anatomia patologica de dos casos de miastenia grave) PEDRO I. ELIZALDE and JUAN R. MANGUILL. *Rev. As. Méd. Argent.* 1947 61: 661

Other authors have found lesions of the thymus gland associated with myasthenia gravis in almost 50 per cent of their cases.

The pathologic findings in 2 cases of myasthenia gravis in which tumors of the thymus were found are reported by the authors. In the first case a thymoeplithelioma was found measuring 4 by 3 cm. in a 40-year-old male. The tumor was ovoid, hard, encapsulated, easily enucleated, of a whitish fatty color and its cut surface showed several small pin-head-sized cavities.

On microscopic examination there was a blastomatous proliferation formed exclusively by epithelial cells with numerous nuclear anomalies which infiltrated the neighboring cellular tissues and reproduced the thymic matrix, and in doing so destroyed the host tissue.

In the second case the thymus was the size of a hen's egg. The cut surface was of a whitish red color and the gland was lobulated in parts. This case was a hyperplasia of the thymus, which on microscopic examination revealed a rich capillary

bed with nuclei far apart and a collagenous mass of the capillaries easily traversed by the thymus cells. In the areas of the capillary anastomoses there were trabeculae of active proliferative thymoblasts. There were also outlines of young epithelial cells, which formed nuclei in concentric patterns, and thymoblasts with acidophilic protoplasm which were homogenous some had clear vacuoles. The process is that of a neoformation in which epithelial cells of the stroma show an intense proliferative activity to which is added the presence of large and small thymic cells.

Neurovascular Syndrome of the Arm Associated with Hypertrophied Subclavius Muscles: Report of a Case Including Operative Treatment.
ROBERT E. CLIFFTON Arch. Surg. 94:7 55 732

A case of dysfunction of the left upper extremity simulating in great detail the scalenus anticus syndrome is presented. In the present case the neurovascular syndrome of the left upper extremity was the result apparently of a hypertrophied subclavius muscle and costocervical fascia secondary to a fractured clavicle which had healed by bony union and without significant deformity 5 years previously.

The symptoms and findings persisted from the time of the accident (December 25, 1910) until operative relief was achieved at the Wakeman General Hospital, Camp Atterbury, Indiana (now disbanded) in 1945. Repeated examinations at several Army hospitals preferred the diagnosis of scalenus anticus syndrome.

In repeated examinations at the Wakeman General Hospital by neurologists, neurosurgeons, and orthopedists, the following observations were consistently made:

The general physical condition was essentially normal. This soldier was lean and wiry but had well developed muscles, especially about the shoulders. There was moderate dilatation of the veins of the left arm and shoulder. The left hand and forearm became cyanotic when the arm was dependent, with the cyanosis most pronounced over the hand and wrist and shading off to normal color above the elbow. The left hand was definitely colder than the right. With elevation the cyanosis slowly disappeared in from 3 to 5 minutes and the hand and the arm blanched more and more and remained cold. There was definite weakness of the left arm and hand (60 to 70 per cent) as compared with the right. The patient was able to elevate the arm just to an angle of 90 degrees but was unable to hold it there for more than a few seconds. It then slowly and steadily fell despite evident effort. The radial pulse was of good quality but was completely obliterated with elevation of the arm to an angle of 40 degrees. It then again gradually became apparent at an elevation of 70 degrees, but was obliterated at an elevation of 90 degrees.

Venographic studies were done 30 c.c. of diodrast being used. Roentgenograms were taken after the injection of 1 and 30 c.c. of diodrast, and in 15 sec-

onds after completion of the injection. Because of the complete block still present a fourth roentgenogram was taken about 10 minutes after the development of the previous 3 roentgenograms. This showed a complete obstruction still present, with moderate collateral filling of the veins. At operation a large hypertrophied subclavius muscle appearing to be two to three times the usual size, was found. As the subclavius muscle was rolled out from beneath the clavicle it was noted that distention in the cephalic and subclavian veins was released. The brachial plexus, the subclavian and axillary arteries and the subclavian and axillary veins were carefully explored from well above the clavicle to below the insertion of the pectoralis major and no other unusual condition was noted.

Dysfunction of an upper extremity due to pressure on vascular and nerve elements in the region of the shoulder are not uncommon and are disabling. It is likely that a predisposing cause lies in an unusual anatomic relationship with narrowing of the costoclavicular space and/or enlargement and hypertrophy of the subclavius muscle, and hypertrophy of the costoclavicular fascia, or in some instances, of the subscapularis muscle. Diagnosis is made by observation of the typical symptoms and signs, and by venographic study which gives a typical picture of obstruction of the flow of opaque medium, usually in the region of the clavicle and first rib, and filling of collateral channels. Operation is believed to be justifiable in a larger number of cases in view of the consistently good results reported. Marked improvement followed the relief of pressure by section of the subclavius muscle in this patient.

JOHN H. MORRIS, M.D.

The Intracellular Mode of Action of the Sulfonamide Derivatives. R. A. Q. O'NEILL, P. A. MC NALLY and H. G. NELSON. *Lancet*, Lond. 1947: 747

How sulfonamides interfere with bacterial metabolism has been studied by the authors in experiments utilizing *Bacterium coli* in urine as a culture medium, and *Streptococcus pyogenes* in meat-extract-peptone broth, to both of which were added 0.3 per cent glucose and 0.1 per cent sodium bicarbonate. Sulfonamides produce their characteristic effects on bacteria by interfering with their metabolism in the so-called "logarithmic" or most rapid phase of bacterial growth. During this phase of maximum bacterial metabolism one of the metabolites produced is a diol compound, probably glucoreductone, which is unstable and highly reactive but unites readily with para-aminobenzoic acid to form a stable, nonreactive compound. This is readily hydrolyzed, when it liberates its original components. Therefore para-aminobenzoic acid appears to be a stabilizing agent which enables the bacterial cells to store glucoreductone as it is formed and to utilize it as it is required. In so doing it prevents the loss of an intermediate metabolite essential during growth and keeps this reactive sub-

stance from exerting a toxic effect on the cells. Other aldehydes and ketones may be similarly stabilized by condensing them with para-aminobenzoic acid. The importance of glucoreductone to bacterial growth has been demonstrated by finding that the acid is utilized by streptococci as a source of growth energy.

The sulfonamides condense with glucoreductone almost as readily as does para-aminobenzoic acid. Their condensation products are not utilizable by streptococci as a source of energy for growth. It is believed that the sulfonamides act within the bacterial cells during their active metabolism by combining with glucoreductone (and possibly other active metabolites) and thus render it unavailable for use by the cells. This deprivation may be fatal to the cells during their active growth for the entire cellular metabolism is suddenly stopped at the very point where it has become adjusted for the special purpose of reproduction.

BENJAMIN F. LOUNSBURY M.D.

Absorption of Penicillin Given by Mouth II C SEIZWART AND J. R. MAY *Lancet* Lond 1947 2 85

The various factors believed to influence the absorption and excretion of penicillin when taken by mouth were investigated carefully in 16 adult healthy males without evidence of infection. A standard dose of 15,000 units administered in about 4 ounces of water was usually used and the subjects were quickly found to be good or poor absorbers of penicillin. The greatest absorption occurred in the duodenum and jejunum with none of significance occurring in the buccal mucosa. It is greatest in the absence of food, although satisfactory levels may be obtained if meal. To cause any appreciable destruction of penicillin within 40 minutes the gastric juice must be of a pH of 3 or less. This time factor is important because in 13 of 15 experiments in 6 persons the peak blood level was found to have occurred at or before this time. Therefore, unless the gastric juice is of a pH of 3 or less no significant destruction can be attributed to it by the time the peak blood level has been reached. Since the number of persons with a resting gastric pH of 3 or less appears to be considerably less than the number of persons who absorb penicillin indifferently it seems unlikely that destruction of penicillin by acid gastric juice can be the only factor concerned.

The use of antacids appeared to be of benefit only in preventing the gastric contents from being at a pH of 3 or less although it is pointed out that slightly alkaline fluids traverse the stomach more rapidly than do acid ones. Thus the use of antacids may facilitate absorption as much by favoring the rapid passage of the drug into the small intestine as by neutralizing the gastric acidity. The water soluble ones are of greater usefulness than the insoluble ones, and indeed kaolin and magnesium trisilicate were found to cause the penicillin to be adsorbed by

them and to adhere to the gastric mucosa. Capsules gave no greater blood levels. Enteric coated ones gave lower values possibly by causing the penicillin to be liberated farther down the gut in an area of poor absorptive power.

Duodenal aspirations revealed no penicillinase and ileal contents save for insignificant amounts in the latter. The authors conclude that it seems very unlikely that penicillinase activity could play any part in the absorption of penicillin by mouth. Of penicillin types I, II, III, and K, no one type was better absorbed than the others. The combination of glucose with penicillin was disappointing although in a few instances the levels were higher and better maintained. Glucose did not produce a consistent improvement in the poor absorbers however. McDermott has stated that in order to produce satisfactory levels with oral penicillin 5 times the dose of intramuscular therapy must be utilized. Because of the possibility that one may be dealing with a poor absorber these authors believe that at least 10 times the intramuscular dose should be used when oral administration is utilized.

If penicillin is to be given by mouth the following suggestions are made: it should be given in about 4 ounces of water with about 30 gr of sodium bicarbonate or citrate before meals and not less than 3 hours preferably 4 hours after the previous meal. The dose should be 10 times as great as the dose of intramuscular penicillin that produces the desired blood level. If this is to be maintained continuously a dose of 500,000 units by mouth should be satisfactory.

The most important factor influencing the absorption of penicillin seems to be the unexplained individual variations in the absorptive capacity of the gut.

ALLAN D. CALLOW M.D.

Sarcoidosis: A Clinical and Roentgenologic Study of 28 Proved Cases. JAMES J. MCCORT, RICHARD HUGH WOOD, JOHN B. HAMILTON, and DAVID E. ENGLISH. *Arch Int Med* 1947 80 793

While serving in an army general hospital functioning as a center for radiation therapy the authors proved clinically and histologically 28 cases of sarcoidosis. They state that the most pressing problem in the diagnosis of a mediastinal tumor is the differentiation of benign from malignant lymphogranuloma. The factors bearing on this differential diagnosis are presented in this article.

Little is known of the pathogenesis of the disease. Tubercle bacilli have been found by several workers in sarcoid lesions and concomitant diseases are still under question. Tubercle bacilli in sarcoid lesions have been reported by several writers. In a number of cases followed up over a period of years frank tuberculosis has been seen to develop in conditions clinically and histologically diagnosed as sarcoid. The development of tuberculosis is one of the frequent causes of death and the relationship is thought

to be more than coincidental by most writers but definite proof of the tuberculous nature of sarcoid is still lacking. Sarcoid lesions have been found in the tonsils, brain, spleen, lung, myocardium, pericardium, kidney, small intestines, testicles, and epididymis.

In all the cases presented in this article the diagnosis was made by histologic examination and confirmed by the Army Medical Museum. Enlargement of the peripheral lymph nodes is common and accessible lymph nodes can be removed easily. The cervical nodes have been the optimum site of biopsy in the authors' cases. The authors recommend a voiding the inguinal glands. They have successfully removed biopsy material from the tonsils, parotid glands, lacrimal glands, skin and mediastinum. Aspirate on biopsy from the liver has been reported as very successful when other sources were not available.

Microscopically there is proliferation of the epithelioid cells with the formation of granulomas. Giant cells of the Langhans type are present. In the lymph nodes the granulomas are arranged in clusters which may fill the entire node, but they usually do not break through the capsule. The center of these tubercles may show slight necrosis, but true caseation is rare.

There is no evidence of depression of hemopoiesis in the bone marrow. In the liver it has been found that the lesions of sarcoid are more numerous in the portal triads.

The manifestations of this disease are many and varied because of the number of organs and tissues which may be involved. About four clinical types are recognized: (1) with sarcoids of the skin; (2) with neoplasms of the skin; (3) with lymphadenopathy of the superficial or intrathoracic nodes, and (4) primary involvement of the pulmonary parenchyma, as shown by roentgenograms which may closely resemble those of pulmonary tuberculosis.

The patients whose cases are presented were admitted to an army general hospital between July 1, 1943 and April 1, 1946. All the patients had intrathoracic lymphadenopathy and all except 3 had enlargement of the superficial lymph nodes. Because of the selection 7 were men (in other series the sex incidence is equal). The majority of the patients have been in the young adult group. It is significant that 15 of the 38 patients were negroes which is in accord with the experience of other investigators.

The symptoms these patients presented were variable in degree but tended to be mild. Nine patients had cough which was persistent and only slightly productive. Only 3 had slight hemoptysis. 1 complained of dyspnea aggravated by exertion and 6 of them lost significant weight. Weakness, fever, anorexia, nausea, and vomiting were occasional symptoms. Six patients had no symptoms whatsoever. It was observed that cough and dyspnea were the most frequent presenting symptoms probably because all the patients had intrathoracic disease. Peripheral lymph nodes were enlarged in 26 of the 38

cases. The nodes were small and discrete and were not confluent. The nodes were often insignificant although they were found to be involved. Eleven patients had eye involvement, most often a uveitis or iridocyclitis, but any or all of the eye structures may be involved. Moderate enlargement of the spleen was found in only 3 cases. There was a low incidence of cutaneous lesions. The fever was usually of low grade and continued over several days or weeks, lasting 3 months in one case.

The most consistent laboratory observation is that the tuberculin skin test is negative in the majority of cases. When a positive reaction occurs it is usually weak and it occurs only with the higher concentrations. This test is valuable in a differential diagnosis. Another significant symptom is the elevation of the globulin fraction of the blood protein. It was elevated in 23 of 38 patients in this series. No instance of a false positive reaction to a serologic test for syphilis was noted. There were no other significant laboratory findings.

In all 38 patients there was evidence of intrathoracic lymphadenopathy which is not easy to detect. Examination should include careful roentgenoscopy with swallowed barium. A posteroanterior and a lateral view and if necessary oblique views should be taken. Usually nodes of 1 cm. or greater in diameter will be detected. In this series most nodes ranged between 2 and 5 cm. in diameter. Like the peripheral nodes, the intrathoracic nodes tend to remain discrete and have a tendency to coalesce. In the roentgenogram the tumor will show a lobulated border giving strong evidence that it consists of a group of enlarged lymph nodes. Calcification in or about the nodes was noticed but once. In no instance was there evidence of lobular collapse. There was no involvement of the esophageal wall or involvement of the phrenic nerves, which is not unusual in bronchiogenic tumor.

Enlargement of the intrathoracic lymph nodes is found in the vast majority of cases of sarcoidosis. In contradistinction intrathoracic lymphadenopathy is a less frequent finding in malignant lymphoma. Later in sarcoidosis the nodes regress slowly and spontaneously to be replaced by fibrous tissue. This has been confirmed by autopsy. In malignant lymphoma the process tends to break through the capsule and invade the surrounding structures.

The roentgenographic appearance of the chest in erythema nodosum can be confused with sarcoidosis, as can pulmonary coccidioidomycosis; however the skin test for coccidioides is helpful for diagnosis.

In this study the earliest manifestation of the disease seemed to be enlargement of the intrathoracic lymph nodes. After a variable time, these tend to regress spontaneously while parenchymal involvement apparently increases. About equal involvement of both lungs is the rule.

No definite pattern of lung changes in sarcoidosis can be predicted. Pulmonary parenchymal involvement was seen in 15 of the 38 cases, the true incidence probably being higher than this figure. Lung

involvement is of two main types which are frequently coexistent. The first and commonest is reticular with thin strandlike areas of increased density extending out from the hilus. Less frequently a nodular increase in density throughout both lung fields is observed and may be confused with milary tuberculosis. In this series the authors were unable to correlate the degree of pulmonary involvement with the severity of the symptoms.

Involvement of the heart and its covering has been reported and 1 patient of this series had pericardial effusion requiring 4 pericardial taps. Two patients had slight pleural effusion. There was no involvement of the bony thorax. Six patients had lesions in the bones of the hands. None was found in the feet or any long bones. None of the patients with hand involvement had symptoms.

Treatment was not discussed except that after 2 patients were given radiation therapy the authors concluded that it was of no value in the treatment of the enlarged lymph nodes of sarcoidosis.

There was but 1 death in this series due to failure of the right side of the heart secondary to extensive infiltration of the lung.

GENERAL BACTERIAL, PROTOZOAN AND PARASITIC INFECTIONS

Staphylococcal Infection Due to Penicillin Resistant Strains. MARY BARBER. *Bris M J* 1947 3 863.

The incidence of strains of the *Staphylococcus pyogenes* that are grossly resistant to penicillin is increasing so rapidly as to be somewhat alarming. In a previous study of 200 patients yielding cultures of the *Staphylococcus pyogenes* penicillin resistant strains were isolated from 25 (12.5%). In a recent series of 100 patients with *Staphylococcus pyogenes* infection 35 yielded penicillin resistant strains.

The degree of resistance in all 38 cases was gross and all except one strain which was not tested were shown to produce penicillinase. Thirty-six of the patients had a sensitivity to streptomycin 2 not being tested and 1 being treated for tuberculous meningitis with streptomycin to which there was resistance. In most of the 38 cases, the *Staphylococcus pyogenes* was the only or at least the pre-dominant organism isolated. In 10 patients, both penicillin-sensitive and penicillin resistant strains of the *Staphylococcus pyogenes* were isolated from the same specimen.

The main cause for this increase in penicillin resistant strains of the *Staphylococcus pyogenes* is the widespread use of penicillin although a patient yielding such an organism may not himself have ever had any. As stated in a previous publication the author believes these strains are not originally sensitive *Staphylococci* which have acquired a resistance to penicillin by contact with it, but are naturally resistant strains which survive by a simple process of selection in penicillin treated infections. That such changes in bacterial flora take place during the

course of penicillin treatment is becoming increasingly clear and is well illustrated by 5 cases of lung infection.

In some cases penicillin resistant organisms are clearly present but are overgrown by sensitive strains until penicillin treatment leaves them a clear field by getting rid of the latter. In any hospital using large quantities of penicillin bacteria resistant to its action are probably increasing at the expense of those that are sensitive. This is illustrated by the fact that in a particular unit of the hospital the percentage of penicillin resistant strains was higher throughout the two investigations, which showed that a penicillin resistant strain of the *Staphylococcus pyogenes* once it gains a foothold in the hospital may spread from patient to patient.

The best method for the detection of penicillin resistant bacteria is to plate out the infected material directly on to a penicillin ditch-plate with a concentration of about 10 units of penicillin per milliliter of agar in the ditch. By this method some information as to both the degree and the type of resistance is obtainable.

EXPERIMENTAL SURGERY

The Role of Leucotaxine in the Production of the Anhydremia of Burn Shock. H. CULLUMBER, F. McDONALD and M. M. SIMPSON. *J Path. Bact., Lond.*, 1947 50 467.

A polypeptide of comparatively low molecular weight and capable of causing increased capillary permeability has been described in inflammatory exudates from various sources. This polypeptide was called 'leucotaxine' and appears to be liberated after injury at the site of the local damage. None has been detected in the blood of burned animals and it is known to be destroyed on incubation with blood serum or plasma. Its local production at the site of injury might be a factor in the causation of the decreased blood volume and anhydremia found in burn cases. The experiments reported here were designed to see if the systemic picture of anhydremia could be reproduced by the localized injection of crude preparations of leucotaxine into the skin. Also observations on the toxic properties of the edema fluids produced by the subcutaneous injection of leucotaxine and by burning have been made.

The methods are described with the use of rabbits. The average results show that the groups of burned rabbits and of those receiving fibrin or skin leucotaxine hypodermically show substantially the same blood picture. The red blood cell count, the blood hemoglobin content, and the blood specific gravity all show a marked increase within 4 hours of injection or burning. This increase is followed by a fall to lower than preinjection or preburning levels. Similarly, both the burning of the skin and the subcutaneous injection of leucotaxine are followed by a marked rise in the blood sugar level, a more sustained rise in the blood urea level, and a fall in the plasma protein content.

Control groups of rabbits receiving isotonic saline hypodermically or nembutal intraperitoneally did not exhibit this blood picture. Neither did a group which received 60,000 units of fibrin leucotaxine intravenously. Here, if anything, a picture of hemodilution was produced.

It can be said that about 60,000 units of leucotaxine can be extracted from 150 sq. cm. of rabbit skin burned at 70° C. for 90 seconds, and that the subcutaneous injection of 60,000 units of this leucotaxine into normal rabbits causes marked local edema and reproduces substantially the blood picture that follows burning of the skin.

The authors confirmed the results of Wilson *et al.* who have described the toxic properties of the edema fluid obtained from the burned skin of rabbits. It would seem that the edema fluid produced by the subcutaneous injection of leucotaxine contains a factor with a toxicity similar to that found after burning. The toxic factor in the edema fluid is not found up to 24 hours after burning but is usually present after 48 hours. GEORGE W. RICHARDSON, M.D.

Development of an Artificial Kidney: Experimental and Clinical Experiences. GORDON MURRAY EDMUND DELORME, and NEWELL THOMAS. *Arch. Surg.* 94:7 55 505

The authors report deals with the development of an artificial mechanical kidney the function of which is to remove from the blood stream circulating toxic substances. The present investigation was based on experiments performed in 1933, 1934 and 1935 with moderate success, using heparin as an anticoagulant and kidney transplantation from one animal to another and from one species to another.

It seemed possible that if a patient could be protected from death from toxemia in such conditions as acute poisoning by mercury and phenol in the tox-

emia of acute infection, such as nephritis or pneumonia with oliguria or anuria, as well as in acute anuria following blood transfusions, administration of excessive sulfonamide drugs, eclampsia and toxemia of pregnancy, severe cutaneous burns, induced abortions and acute injury to ureters and kidneys from calculous obstruction reflex or otherwise, or operation after a time there would be sufficient recovery in a number of cases so that the affected kidneys might resume function.

After extensive and arduous trials and experiments, an apparatus was finally devised and described which apparently works smoothly for long periods and performs the functions for which it was developed. The successive stages in perfecting the apparatus are described.

A detailed description is given of a patient who had anuria for 9 days secondary to an attempt at induced abortion. During this period the patient was passing about 35 c.c. of urine daily and when first seen had uremia, was comatose, edematous, and having mild uremic convulsions. The condition seemed hopeless. On the ninth day the patient was attached to the artificial kidney by passing a catheter through the saphenous vein into the inferior vena cava on the right side and another into the femoral vein on the left. With repeated runs, the patient recovered and is now in good health.

A report is made, after a great deal of experimental work, of an artificial kidney or dialyzing membrane which has been used in such a way that it can be applied safely to animals or to human beings. This membrane can be used to remove toxic substances from the blood. With proper huffing of the dialysate there are no injurious effects as a result of this dialyzing process. A clinical case is described in which cure was effected.

THE HEALING OF BOWEL AS INFLUENCED BY SULFASUXIDINE AND STREPTOMYCIN

EDGAR J POTH M.D. Ph.D. F.A.C.S. JOSEPH P McNEILL, M.D.

LOUIS J MANHOFF, Jr. M.D. WALTER B KING M.D. and

JOHN G SINCLAIR Ph.D. Galveston Texas

THE value of sulfasuxidine and sulfathalidine since their introduction as intestinal antiseptics in 1941 (1) and 1943 (2) respectively has been repeatedly and amply demonstrated in both the clinical and experimental use of these bacteriostatic agents. Oral streptomycin has been suggested for a similar purpose more recently by Zintl, Wiley Nichols and Rhoads.

It has been demonstrated previously that these sulfonamides favor the healing of the colon in dogs (3) following anastomosis. Now with the introduction of streptomycin as an intestinal antiseptic to effect an alteration of the bacterial flora its influence upon bowel healing is likewise being studied. Two types of anastomosis are studied. Series A an open technique using a single, continuous row of chromic catgut placed through the entire thickness of the wall of the colon and Series B a so-called aseptic procedure using two rows of sutures which include the submucosa but which do not penetrate the mucosa.

PROCEDURE

Forty four selected dogs are divided into two groups and placed on a diet of ground

From the Surgical Research Laboratory and the Department of Anatomy University of Texas Medical Branch, Galveston, Texas.

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, New York, September 8-11, 1947.

horse meat. Series A consisting of 30 animals and Series B of 14. These two series are each further divided into three: one portion to serve as controls, a second one to receive sulfasuxidine only and the others sulfasuxidine plus streptomycin.

The operative procedures used in Series A and B are illustrated in Figures 1 and 2 respectively.

The control animals for each series A and B received ground horse meat for 12 days preoperatively, a purge of magnesium sulfate the evening before operation and a diet of horse meat postoperatively after 24 hours.

The animals which received only sulfasuxidine were placed on a similar diet. They received 10 gram of sulfasuxidine per kilogram of body weight daily mixed with the meat which was divided into 6 portions and fed at 4 hour intervals for 12 days preoperatively and postoperatively after 24 hours.

In the case of the 12 animals receiving both sulfasuxidine and streptomycin the schedules were somewhat varied. At first it was desired to give streptomycin alone but it became evident immediately that the bacterial count while it was readily reduced, could not be maintained at a decreased figure (Chart 1). Therefore to test whether or not streptomycin altered bowel healing and to make a comparison with the other treated animals in this

Control groups of rabbits receiving isotonic saline hypodermically or nembutal intraperitoneally did not exhibit this blood picture. Neither did a group which received 60,000 'units of fibrin leucotaxine intravenously. Here, if anything a picture of hemodilution was produced.

It can be said that about 60,000 units of leucotaxine can be extracted from 150 sq. cm. of rabbit skin burned at 70° C. for 90 seconds and that the subcutaneous injection of 60,000 'units of this leucotaxine into normal rabbits causes marked local edema and reproduces substantially the blood picture that follows burning of the skin.

The authors confirmed the results of Wilson *et al.* who have described the toxic properties of the edema fluid obtained from the burned skin of rabbits. It would seem that the edema fluid produced by the subcutaneous injection of leucotaxine contains a factor with a toxicity similar to that found after burning. The toxic factor in the edema fluid is not found up to 24 hours after burning but is usually present after 48 hours. GEO. DE W. RICHARDSON M.D.

Development of an Artificial Kidney: Experimental and Clinical Experiences. GORDON MURRAY EDWARDS DEXTER, and NEWELL THOMAS. *Arch. Surg.* 94: 55 505

The authors report deals with the development of an artificial mechanical kidney the function of which is to remove from the blood stream circulating toxic substances. The present investigation was based on experiments performed in 1933 1934 and 1935 with moderate success, using heparin as an anticoagulant and kidney transplantation from one animal to another, and from one species to another.

It seemed possible that if a patient could be protected from death from toxemia in such conditions as acute poisoning by mercury and phenol, in the tox-

emia of acute infection, such as nephritis or pneumonia, with oliguria or anuria, as well as in acute anuria following blood transfusions, administration of excessive sulfonamide drugs, eclampsia and toxemia of pregnancy severe cutaneous burns, induced abortions and acute injury to ureters and kidneys from calculous obstruction reflex or otherwise, or operation after a time there would be sufficient recovery in a number of cases so that the affected kidneys might resume function.

After extensive and arduous trials and experiments, an apparatus was finally devised and described which apparently works smoothly for long periods and performs the functions for which it was developed. The successive stages in perfecting the apparatus are described.

A detailed description is given of a patient who had anuria for 9 days secondary to an attempt at induced abortion. During this period the patient was passing about 35 c.c. of urine daily and when first seen had uremia was comatose edematous, and having mild uremic convulsions. The condition seemed hopeless. On the ninth day the patient was attached to the artificial kidney by passing a catheter through the saphenous vein into the inferior vena cava on the right side and another into the femoral vein on the left. With repeated runs, the patient recovered and is now in good health.

A report is made, after a great deal of experimental work, of an artificial kidney or dialyzing membrane which has been used in such a way that it can be applied safely to animals or to human beings. This membrane can be used to remove toxic substances from the blood. With proper buffering of the dialysate there are no injurious effects as a result of this dialyzing process. A clinical case is described in which cure was effected.

THE HEALING OF BOWEL AS INFLUENCED BY SULFASUXIDINE AND STREPTOMYCIN

EDGAR J. POTH, M.D., Ph.D., F.A.C.S., JOSEPH P. McNEILL, M.D.
LOUIS J. MANHOFF, Jr., M.D., WALTER B. KING, M.D., and
JOHN G. SINCLAIR, Ph.D., Galveston, Texas

THE value of sulfasuxidine and sulfathalidine since their introduction as intestinal antiseptics in 1941 (1) and 1943 (2) respectively has been repeatedly and amply demonstrated in both the clinical and experimental use of these bacteriostatic agents. Oral streptomycin has been suggested for a similar purpose more recently by Zimtel, Wiley, Nichols, and Rhoads.

It has been demonstrated previously that these sulfonamides favor the healing of the colon in dogs (3) following anastomosis. Now with the introduction of streptomycin as an intestinal antiseptic to effect an alteration of the bacterial flora, its influence upon bowel healing is likewise being studied. Two types of anastomosis are studied: Series A, an open technique using a single, continuous row of chromic catgut placed through the entire thickness of the wall of the colon; and Series B, a so-called aseptic procedure using two rows of sutures which include the submucosa but which do not penetrate the mucosa.

PROCEDURE

Forty-four selected dogs are divided into two groups and placed on a diet of ground

From the Surgical Research Laboratory and the Department of Anatomy, University of Texas Medical Branch, Galveston, Texas.

Presented at the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, New York, September 8-7, 1947.

horse meat. Series A, consisting of 30 animals; and Series B, of 14. These two series are each further divided into three: one portion to serve as controls; a second one to receive sulfasuxidine only; and the others sulfasuxidine plus streptomycin.

The operative procedures used in Series A and B are illustrated in Figures 1 and 2 respectively.

The control animals for each series A and B received ground horse meat for 12 days preoperatively; a purge of magnesium sulfate the evening before operation; and a diet of horse meat postoperatively after 24 hours.

The animals which received only sulfasuxidine were placed on a similar diet. They received 1.0 gram of sulfasuxidine per kilogram of body weight daily mixed with the meat which was divided into 6 portions and fed at 4-hour intervals for 12 days preoperatively and postoperatively after 24 hours.

In the case of the 12 animals receiving both sulfasuxidine and streptomycin, the schedules were somewhat varied. At first it was desired to give streptomycin alone, but it became evident immediately that the bacterial count, while it was readily reduced, could not be maintained at a decreased figure (Chart 1). Therefore, to test whether or not streptomycin altered bowel healing and to make a comparison with the other treated animals in this

Chart The characteristic changes in the bacterial flora of the bowel of the dog following streptomycin administration in large doses are illustrated graphically. The coliform organisms decreased rapidly at first, but then they increased in resistance 3,000 fold. Following this increased resistance sulfasuxidine was still somewhat effective; the organisms showed increased resistance to this drug also.

study it was necessary to alter the bacterial flora with sulfasuxidine in the usual manner. Six of these animals received streptomycin for 33 days preoperatively. Another group of 6 animals received sulfasuxidine for 10 days plus sulfasuxidine and streptomycin for 2 days preoperatively and then both drugs postoperatively after 24 hours (Chart 2).

The animals which survived were sacrificed at 3, 5 and 7 days postoperatively at which time a complete autopsy was performed, colored photographs of all specimens taken, and the operative specimens preserved in 10 per cent formalin for subsequent microscopic section and study.

RESULTS

Series 1. Open anastomosis. The difference between the treated and control groups of experiments is characteristic, constant and easily recognized. The abdominal wounds of the animals which had received preoperative ther-

apy with sulfasuxidine or with sulfasuxidine plus streptomycin healed rapidly without evidence of infection in contradistinction to the controls in which edema, inflammation and infection were ordinarily present. Also when the abdomen was opened the control experiments were characterized by a diffuse peritoneal reaction, dense edematous adhesions of omentum and adjacent loops of bowel to the site of the anastomosis; the treated animals showed no evidence of peritonitis, and adhesions and edema were minimal.

On removal of the operative specimen great care was required to avoid disruption at the line of suture of the untreated colon. The specimens from the treated animals could be handled freely and required considerable pull to cause separation of the anastomosis. Opening the colon specimens longitudinally revealed a remarkable difference in the extent to which edema existed (Figs. 3 and 4). The edema of the mucosa extending 5 to 7 cent

Fig 1 Open anastomosis (Series A) of descending colon of the dog. A single continuous row of No. 00 chromic catgut is placed through and through the full thickness of the bowel wall. A single interrupted suture of No. 00 chromic catgut is used to bury the knot of the continuous suture tied at the antimesenteric border.

Fig 2 Closed, aseptic anastomosis (Series B) of descending colon of the dog. An inner continuous row of No. 00 chromic catgut is placed so as to include the submucosa without entering the lumen of the bowel as indicated. A second anterior and posterior row of interrupted fine black silk is placed to include the submucosa but not penetrate into the lumen.

meters on either side of the suture line in the controls was sufficient to cause from 50 to 90 per cent obliteration of the lumen of the colon. In contrast the edema in the mucosa of the treated animals was limited to within 2 centimeters of the line of suture and seldom caused as much as a 25 per cent reduction of the lumen of the bowel.

Grossly there was no difference between those animals receiving sulfasuxidine only and those receiving both sulfasuxidine and strepto-

mycin. Although gross infection was usually present and 3 of the 12 control animals died of peritonitis following perforation the most remarkable differences are evident upon microscopic study of the tissues at and near the anastomosis (Figs 5, 6, 7 and 8).

Series B Closed or aseptic anastomosis. The results in the control experiments in this series were superior to the controls of Series A. No deaths occurred. Nevertheless the process of healing in the treated and untreated

Fig 6

Fig 6. Control experiment same as shown in Figure 5 except that the specimen is taken on the 5th postoperative day. The formed cellular elements continue to be largely polymorphonuclear leucocytes with an occasional early fibroblast. Revascularization has not occurred.

Fig 7. Microscopic section $\times 380$ taken from the line of suture (Series A) from the colon of a dog which had received the standard ground meat diet and sulfasuxidine 2.0 gram per kilogram daily in 6 divided doses for 12 days preoperatively and again postoperatively after 24 hours until the animal was sacrificed on the 3rd postoperative day. Fibroplasia is proceeding in an orderly manner with well advanced revascularization. There is moderate polymorphonuclear infiltration.

Fig 7

Fig 8. Same as Figure 7 except that the specimen was taken on the 5th postoperative day. Healing is continuing with orderly fibroplasia and revascularization. An occasional polymorphonuclear leucocyte remains in the healing tissue.

Fig 8

The difference of healing between the control and treated animals is so striking as to resemble secondary repair in the first instance and primary healing following the alteration of the bacterial flora.

The mechanical aspects of fecal material remaining in the bowel at the time of operation are important. In these experiments the long period of low residue diet magnesium sulfate given the control animals 12 hours before operation and a large dose of morphine 1 hour preceding anesthesia completely emptied the colon of the control animals. The treated animals received no purgation and a small quantity of liquid fecal material was present. No attempt was made to avoid gross soiling dur

The same dietary and drug regimen postoperatively after 24 hours until the animal was sacrificed 3 days postoperatively. The arrows indicate the extent of the gross edema on either side of the line of anastomosis. There is clean healing at the line of suture.

Fig 4. Specimen P 35. Mucosal surface of the colon (control). Dog on ground meat for 12 days preoperatively and postoperatively after 24 hours. Animal sacrificed 3 days postoperatively. The arrows indicate the extent of the gross edema on either side of the line of anastomosis. Distance of 3 to 4 centimeters. There are ulcers at the line of suture.

Chart 2. Sulfasuxidine, 20 gram per kilogram daily in 6 divided doses for 3 days, then 10 gram per kilogram daily of streptomycin was given orally in addition to the sulfasuxidine for 2 days, the bowel section and suture done, and the sulfasuxidine and streptomycin given postoperatively after 24 hours until the animal was sacrificed. By this dosage schedule it was hoped to have the maximum antibacterial effect at the time of operation with the most favorable conditions for healing. Healing was no better than with sulfasuxidine alone.

animals was vastly different. The control groups always showed infection and delayed healing while the process of repair in the treated groups closely resembled primary uncomplicated healing with orderly fibroplasia and revascularization (Figs. 5, 6, 7 and 8).

The gross appearance of Series B was little changed from that of Series A except for the effect of the larger inverted cuff due to the use of clamps and two rows of sutures, and for the fact that in Series B the mucosa was not as well healed and ulcerated areas were present for the first 5 days postoperatively.

DISCUSSION

The operation of bowel suture always results in contamination of the tissues which are being approximated. It is possible to avoid visible soiling but bacterial contamination of the innermost edges of the apposed bowel wall occurs during the first few minutes after the inner row of sutures is applied even though a closed aseptic technique be used. Consequently healing of the colon following anastomosis must simulate that of a contaminated wound. This fact is quite conclusively demonstrated in the microscopic sections taken across the suture line. The lessened extent to which this occurs when the bacterial flora has been simplified and attenuated by intestinal antiseptics must account for the improvement and rapidity of healing observed following the administration of sulfasuxidine (Table I).

INTESTINAL INTUBATION IN SMALL BOWEL DISTENSION AND OBSTRUCTION

Further Experiences with the Single Lumen Mercury Weighted Tube and Analysis of Complications

FRANKLIN J. HARRIS, M.D., F.A.C.S., and MILLER GORDON, M.D., San Francisco, California

The remarkable improvement which has occurred in the last decade in the treatment of bowel obstruction is due largely to three factors: (1) earlier diagnosis because of more general use of x-ray and knowledge obtained from flat film of the abdomen in suspected cases; (2) better understanding and treatment of the disturbed physiology in obstruction and (3) development in the nonoperative relief of bowel distention by intubation. Credit for the introduction of the principle of suction decompression of the intestines belongs to Robertson Ward and to Wangensteen and Paine (19). However, popularization of this method came after the development by Miller and Abbott in 1934 of the double lumen balloon tipped long intestinal tube. The surgical literature emphasizes the value of intubation as a means of treatment of obstruction and as an adjunct in minimizing distention associated with preoperative and postoperative obstruction. Beverly C. Smith, reporting on 1000 cases of intestinal obstruction in which the Miller Abbott tube was used, noted improvement in 786. Smith stated that 444 of these cases did not require operation because of lasting decompression and restoration of function provided by successful intubation. Failure to pass the pylorus was recorded in 221. Eliason and Welty in a 10 year survey of obstruction analyzed 292 cases; they found that intubation was used in 124 and eliminated the necessity for operation in 25 per cent of this group.

Utilization of intestinal intubation has been restricted because of the relative difficulty

involved in securing passage of the double lumen Miller Abbott tube through the pylorus. It was recognized that a method which provided more rapid passage of the tube was desirable. In 1941 the senior author began experimenting with liquid metallic mercury introduced into the balloon of the Miller Abbott tube to facilitate its descent. Results were so satisfactory that a preliminary report was deemed justified and appeared 3 years later (10) about the time other investigators were working independently with mercury as an aid to intubation. Wild in England presented his mechanism consisting of two tubes, a bag for inflation and an additional gravity direct or head or bag containing mercury introduced by mouth. At the time his report was published he was planning a double lumen tube. Iver Sivertsen of Minneapolis suggested to Wangensteen the use of mercury in the Miller Abbott tube but lacked clinical material to experiment with the method.

In his preliminary report in 1944 the senior author indicated that a new intestinal tube was being developed. The tube was single lumen, was weighted with a bag containing mercury and could be readily inserted through the nares into the stomach, thus simplifying the procedure of intestinal intubation. A detailed description of the tube and technique appeared in the December 1945 issue of *SURGERY, GYNECOLOGY AND OBSTETRICS*. This tube which is more easily passed and has a larger caliber to provide for adequate drainage has been a great stimulus to the increased use of intubation of the small intestine and has further confirmed the soundness of the principles of bowel decompression originally advocated by Wangensteen. Difficulties and problems associated with the

Fig. 1. a, left, X ray evidence of abnormal small bowel distention due to mechanical obstruction which developed suddenly on 15th postoperative day in 36 year old male who had had an abdominoperineal resection for perforated carcinoma of rectosigmoid. Harris tube passed too rapidly and it is coiled in stomach. Metallic clip indicates site of colostomy. b, right, Four hours later after tube had been partially withdrawn and allowed to descend spontaneously it is seen entering small bowel and there is beginning relief of distention. Obstruction relieved without operation.

1 to 2 weeks so we are ever cognizant of the possible complication of laryngeal perichondritis and resultant laryngeal stenosis. To avoid pressure necrosis it is advised that the tube be frequently withdrawn a few inches and then allowed to redescend after an interval of time as has been advocated by Holinger and Loeb.

A measured and restricted amount of liquid is allowed by mouth while the tube remains in the stomach. Until such time as the tube has passed into the small intestine we permit a maximum of 4 ounces of water tea or ice chips every 2 hours. Indiscriminate water intake during continuous gastric suction is attended by considerable danger of serious alkalosis. Water intake which is rapidly lost by the suction causes a disproportionate outpouring of salt into the stomach in an attempt to make the liquid isotonic. Withdrawal of this fluid by suction produces a fall in the chloride level of the blood and therefore the kidneys must excrete a proportionate amount of urine containing bicarbonate. Paradoxically allowance of water by mouth *ad libitum* under such circumstances becomes a dehydration measure (3).

FAILURE OF PASSAGE OF THE TUBE

There were 10 cases in which the tube failed to pass the pylorus. A brief analysis of a few of these is given to illustrate some of the minor points in technique.

CASE 1 (No 18185) A. S. female, aged 76 entered the hospital with a history of abdominal distress and fecal type vomiting during the preceding 6 hours. Harris tube passed July 4, 1946 date of entry. Twenty four hours later the tube still remained in the stomach as shown by flat film. Operation revealed mechanical obstruction due to multiple adhesions from previous laparotomy. Tube remained in the stomach for 4 days postoperatively and never passed the pylorus. Postoperative flat films showed relief from distention of the small bowel.

The Harris tube in this case decompressed the stomach. Although it did not pass the pylorus it successfully maintained intestinal decompression in a manner similar to the occasional action of a Levine tube. Failure to pass was probably due to the fact that the patient was not propped up nor was any attempt made to stand her up.

CASE 2 (No 11050) W. T. male aged 14 entered the hospital February 19, 1945 with diagnosis of perforated pelvic appendix with abscess forma-

technique of intubation are still present and we recognize that the Harris tube can and undoubtedly will be further modified and improved. Cantor (4) recently described his experiences with a modification of the tube consisting essentially of an increase in the number of perforations and a change in the placement of the mercury bag. We have had no personal experience with Cantor's modification however Arthur Allen reporting from the Massachusetts General Hospital states that the high openings in the tube are designed to pick up secretions from the stomach as well as from the intestine. It appears that the benefit of the principle of the decompression tube may be lost by this method since the normal secretions above the obstructed loop contain valuable chemical elements that are absorbed if not removed.

It is the purpose of this communication to analyze our experiences with intubation and to advocate certain changes in the structure of the tube and in technique.

COMPLICATIONS ASSOCIATED WITH PASSAGE OF THE TUBE

The method of passage of the Harris tube has been standardized and described (11). A preliminary narcotic either morphine or demerol combined with atropine is administered. A topical anesthetic such as pontocaine alleviates nasal discomfort. The tube is lubricated either with glycerine or a simple lubricating jelly. Mineral oil is never used as a lubricant because of the possibility of lipid pneumonia. The semi Fowler position is preferred. The tube is held up so that the mercury sinks to the proximal portion of the bag which is then twisted around its longitudinal axis in order to decrease its caliber. Air should be expelled from the bag before it is attached to the tube to minimize the hulk that must pass through the nose. The tip of the tube is then inserted into the anesthetized naris for half its length after which the proximal position of the bag and tube are elevated permitting the mercury to flow into the distal portion and aiding the force of gravity to drop the tube down the nasopharynx and into the stomach. After the mercury bag passes the nasopharynx it usually descends rapidly with

out provoking a gag reflex. Occasionally it descends more slowly and may be hastened by small sips of water. As soon as the tube has entered the stomach Wangensteen suction is started and maintained continuously or intermittently. Immediate suction is important as it deflates the stomach and as Wangensteen has shown often deflates the upper small intestine. Slack tubing is attached loosely to the cheek, and it is emphasized to the nursing and house staff personnel that no attempt should be made to push the tube into the intestine. If the tube has been successfully introduced into the stomach, it will pass through the pylorus and into the obstructed bowel unaided by further manipulations, or it will not pass at all. The force of gravity may be further utilized in obtaining passage by allowing the patient to stand up or walk around for a few minutes. If the patient is unable to leave the bed a high semi Fowler position with the patient on the right side is advised.

Coiling of the tube in the stomach preventing entrance into the small bowel was a complication early discovered. Coiling is the result of attempting to hurry the passage of the tube by manually feeding it into the stomach. In the original description of technique it was advised that the tube be moved along at the rate of 1 inch every 10 minutes. However we are now insistent that a 'hands off' policy be adopted and that the tube be allowed to descend spontaneously (Fig 12 and 13). Since this modification in technique has been adopted no coiling in the stomach has occurred. We now insist that progress of the tube downward be stopped at the 3 foot mark until an x ray film has been taken. The reason for this important restriction will be explained later. Attention to small details maintains the comfort of the patient and decreases minor complications such as irritation of the nasal mucosa and superficial ulceration of the naris which may lead to cellulitis. A bland ointment such as vaseline is applied frequently to the nasal mucosa and naris. Chewing gum or hard candy which may be sucked tends to prevent parotitis moistens the pharynx and aids in the prevention of laryngeal irritation. Often the tube must remain in place for from

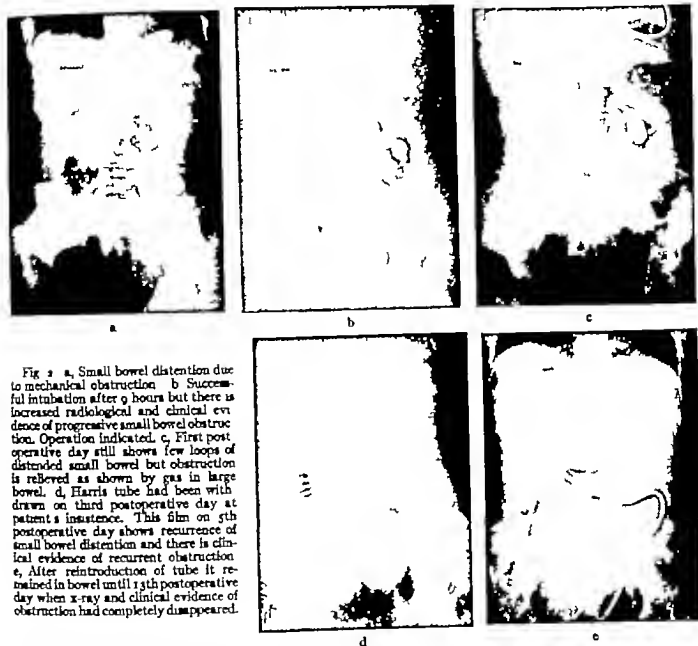

Fig 2 a, Small bowel distention due to mechanical obstruction. b Successful intubation after 9 hours but there is increased radiological and clinical evidence of progressive small bowel obstruction. Operation indicated. c, First post-operative day still shows few loops of distended small bowel but obstruction is relieved as shown by gas in large bowel. d, Harris tube had been withdrawn on third postoperative day at patient's insistence. This film on 5th postoperative day shows recurrence of small bowel distention and there is clinical evidence of recurrent obstruction. e, After reintroduction of tube it remained in bowel until 13th postoperative day when x-ray and clinical evidence of obstruction had completely disappeared.

patient and surgeon some mental anguish. It was therefore decided that the length of tubing to be passed into the small bowel should be limited to 4 feet. Another reason for decreasing the length was found when study of the numerous flat films in this series frequently showed that only 1 or 2 feet of tubing descending beyond the pylorus was sufficient to deflate completely all the loops of small bowel including those in the pelvis. It was also noted in some instances that with only 3 to 4 feet of tubing in the intestines the head occasionally would be seen at or through the ileocecal valve (Fig 3b). As the average total length of small bowel from pylorus to ileocecal valve

varies from 20 to 25 feet we must assume that the small bowel pleats itself on the tubing. This phenomenon we have compared to the principle upon which an accordion operates lengthening or shortening as it is played. This accordion principle has been verified so frequently that we have requested the manufacturer of the Harris tube to shorten it to a total length of 6 feet from its previous 9 foot length. Also we now routinely insist that after the tube has passed the 3 foot mark further progress be restricted until x ray films show its exact position. Two to 3 feet of tubing passed beyond the pylorus is sufficient successfully to decompress the entire small intestine

tion spreading peritonitis and secondary mechanical small bowel obstruction. Diagnosis was confirmed by operation performed the same day. Postoperative failure of passage of the tube was due to the fact that the patient was unco-operative and repeatedly pulled the tube out of his nose. Fortunately postoperative distention was not severe. Patient recovered.

Failure of passage was due to unco-operative patient

CASE 3 (No 17414) C. C. female, aged 53 entered the hospital with the diagnosis of carcinoma of the rectum. Abdominoperineal resection was performed May 28 1946. Harris tube was passed June 2 1946 because of abdominal distention following massive pulmonary infarction. Five days later the tube still remained in the stomach and was withdrawn. A new tube was reinserted and remained in the stomach another 3 days until June 10 1947 when it started to descend into the small bowel. It successfully decompressed loops of small bowel that appeared to be mechanically obstructed.

Failure of passage through the pylorus for so many days was thought to be due to the profound atony of the stomach associated with extreme weakness of the patient who was simultaneously suffering from massive pulmonary infarction and heart failure. We were unable to attempt to move the patient out of bed or to change her position frequently. Final recovery however was definitely aided by the ultimate relief of her small bowel distention by intubation.

CASE 4 (No 21306) J. R. male aged 40 was being treated by peritoneal irrigation according to the method of Fine, Frank and Seligman in an attempt to relieve renal failure due to sulfonamide medication. To relieve the severe small bowel distention an attempt was made to pass the Harris tube January 12 1947. It remained in the stomach until January 14, 1947 and was then withdrawn at the insistence of the patient.

Failure of passage in this case was due to unusual atony of the stomach, general weakness of the patient and inability to maintain an erect position out of bed. Patient expired.

CASE 5 (No 22941) C. K. male aged 53 entered the hospital April 18 1947 with the diagnosis of perforative appendicitis and spreading peritonitis. Operation April 18 1947 revealed generalized purulent peritonitis secondary to perforated gangrenous appendicitis. Harris tube was introduced immediately but after 4 days had failed to pass the pylorus. However postoperative small bowel distention was relieved and the tube was withdrawn.

Failure of passage cannot be explained in this case but intubation of the stomach successfully relieved the moderate postoperative small bowel distention.

DURATION OF INTUBATION

No absolute rule can be made concerning the length of time that intubation should be maintained. In this series the shortest duration was 24 hours, followed by relief in a case of a cord tumor with reflex distention. The longest was 17 days in a case of postoperative small bowel obstruction due to adhesive bands. During a prolonged period of intubation the patient's nutrition may be successfully maintained by oral intake as the decompressed loops of the upper small bowel retain their power of absorption. It has been previously emphasized that frequent flat films of the abdomen must be taken and that the duration of intubation will be determined by roentgenological as well as clinical improvement. The tube is never withdrawn until the patient has been given a fair trial without suction. If abdominal distention does not recur after periods of from 6 to 12 hours free from suction it is a good indication to remove the tube (Case 8 Fig 2d and e).

COMPLICATIONS ASSOCIATED WITH WITHDRAWAL OF THE TUBE

Early in the use of the new tube we noted an occasional case in which the head passed through the ileocecal valve. In such cases it was difficult to withdraw the tube and in one instance we are certain that the persistent attempt to pull the head back through the valve resulted in a tear of the bowel and the production of a localized abscess. It was later decided that when the bag entered the ileocecal valve the tube should be cut at the Paris and allowed to be eliminated per anus or colostomy. There have been seven such cases. No ill effects are associated with passage of the tube through the intestines except for occasional transitory abdominal colic. The time required to expel it varied in different patients; the shortest 24 hours until head of tube presented at anus; the longest (Fig 3) 10 days. This complication, while not serious is nevertheless annoying and may cause both

Fig. 3. a, Head of tube has passed ileocecal valve. Tube was used prophylactically in rectosigmoid resection with end-to-end anastomosis in 72 year old male. Third postoperative day removal of tube attempted. b, Fifth postoperative day head of tube remains caught on distal side of ileocecal valve. Tubing from naris to ileocecal valve measures 3 feet. Tube was cut at naris to allow passage per rectum. This is 7th postoperative day and head of tube is in upper ascending colon. Progress continued and was checked by frequent x-ray films which are not shown here. d, Fourteenth postoperative day head of tube in rectosigmoid anastomosis. e, Fifteenth postoperative day head of tube appears taut and is withdrawn.

It is not necessary for the intestinal tube actually to reach the point of obstruction in order to deflate the bowel. If the tube enters the small bowel it will act on the same principle as an operative enterostomy. Successful intubation is an 'incisionless enterostomy' which will decompress more loops of bowel more rapidly than the operative procedure. However the principle learned from operative enterostomy that a small vent in the distended bowel decompressing a local loop may deflate all the loops above or below is still applicable in intubation. It also offers another reason to explain why 2 or 3 feet of tubing in

the upper small bowel may deflate the entire intestinal tract. The shortened tube can be more easily withdrawn by mouth and the need for it to pass per rectum will be reduced.

In 3 cases the difficulty in removing the tube appeared to be due to an increase in the amount of air or gas in the rubber bag containing mercury causing unusual distention of the bag. This remarkable phenomenon is due to permeability of the rubber condom which permits an exchange of gas into the bag (13). In each case in which this complication occurred the duration of intubation had been more than 10 days. This osmotic process appears to

Fig 5 a, left Mercury bag broke on withdrawal of tube scattering 4 cubic centimeters of metallic mercury in small bowel. This film taken 3 hours after accident. b right Ten days later shows minute globules of mercury still present. No clinical evidence of mercury poisoning

ileus and the only treatment necessary in non occluded cases

These few quotations have been given as a small example of the apparent contradictory indications for intubation. They show the necessity of simplifying and clarifying by a change in terminology the general type of case that is best treated by intestinal decompression. Pending standardization of terminology we believe that more frequent use of the term "small bowel distention" will enable surgeons to visualize the type of patient in whom intubation is particularly indicated. Some patients suffering from medical conditions present severe distention. The problem confronting the surgeon is that of relieving distention which embarrasses circulation and respiration and which if not relieved may be an important factor leading to death. To argue whether distention represents dynamic or adynamic ileus, ileus alone, simple obstruction, mechanical obstruction, or occlusive ileus or obstruction only adds confusion and delays the proper therapeutic approach. In small bowel distention due to causes other than strangulating obstruction intubation is definitely indicated as the first treatment and is often the only treatment necessary. When intubation does not relieve distention completely after a reasonable period of time then

surgery must be considered. In primary strangulating obstructions or obstructions of the colon with great distention of the large bowel it is obvious that surgery is urgently indicated and intubation should not be used as a temporizing agent. There has been no instance in our experience in which delayed operation due to the use of intubation has resulted in a fatality. We do recognize how ever this dangerous possibility and urge most careful observation of every patient being treated by intubation instead of surgery.

A few cases are briefly summarized to illustrate the principle of primary relief of small bowel distention by intubation alone.

CASE 7 (No 21530) W L male 46 entered the hospital on medical service with the diagnosis of acute ventricular tachycardia and heart failure. Severe and embarrassing abdominal distention developed. There were no abdominal scars and it is believed that the small bowel distention was due to edema of the mesentery or wall of the bowel due to heart failure. Intubation was advised and x-ray taken 24 hours after introduction of 3 feet of Harris tube showed complete deflation of the distal loops. Total period of intubation was 6 days.

This case illustrates small bowel distention associated with heart failure and a successful therapeutic result by intubation alone.

CASE 8 (No 16410) S G female aged 42 entered the hospital March 3 1946 complaining of

had not traversed the ileocecal valve. Such a complication proved to be of diagnostic value and was an indication for surgical interference even though there was clinical and radiological evidence of deflation (Case 6)

CASE 6 (No 18836) F G female, aged 37 entered the hospital August 21, 1946, with the diagnosis of perforated appendicitis and peritonitis. Operation the same day confirmed the diagnosis of generalized spreading peritonitis. Appendectomy was performed and the wound was closed without drainage. August 24, 1946, there was radiological and clinical evidence of small bowel obstruction (Fig 4a). Harris tube was passed, August 30, 1946, small bowel distention had been relieved. An attempt to remove the tube was unsuccessful (Fig 4c) and it was decided to attempt to pass per rectum. Figure 4d shows section of the cut tube lying in the small bowel and by August 27, 1946 no further progress of the patient appeared clinically well but operative interference was indicated because of failure of cut Harris tube to move from its original position. At operation August 28, 1946, loops of small bowel were found in the terminal ileum bound down by plastic adhesions and distended. The terminal loop of ileum 1 1/4 feet proximal to the ileocecal valve was bound down in a V-shaped section. A section of Harris tube located within the terminal half of the bag in each arm of the V-shaped adhesions was performed. The bowel opened and the terminal loop inflated. Tube and bag were removed and a W type enterostomy made from the small opening in the bowel. Postoperative course was uneventful.

Inability to withdraw the tube even though it had not passed through the ileocecal valve and failure of cut section of the Harris tube to pass were important diagnostic points. We were convinced this patient had a mechanical small bowel obstruction incomplete but sufficiently severe to threaten catastrophe were it not relieved by surgical means. The osmotic swelling of the bag probably was a contributing factor in the failure of this section of tube to pass completely through the V shaped link in the terminal ileum.

BREAKAGE OF MERCURY BAG

In 4 cases the bag containing mercury ruptured during the process of removing the tube. In these careful study has been made to determine clinically and by laboratory means if there was any evidence of mercury absorption or poisoning. Urine examinations were repeatedly negative and at no time was there mercury toxicity. These findings have been

corroborated by other investigators (5) as well as by earlier experiments on dogs which the senior author performed before originally introducing the use of mercury as a vehicle for the bag of the Miller Abbott tube. The time necessary to empty the bowel of the free mercury present after rupture of the bag varied. In 1 patient (Fig 5 a and b) mercury appeared in globules in the stools for approximately 6 days at the end of which time there was very little x ray evidence of any remaining in the bowel. It has never produced diarrhea. One action of mercury frequently noted is a black discoloration of the rubber bag apparently due to chemical interaction between the rubber and the mercury. We have noted no ill effects from this phenomenon.

INDICATIONS FOR INTUBATION THERAPY

Writers on the subject of intubation have tried to define accurately the type of case in which it is of therapeutic value. Considerable confusion exists because of the wide variety of terms used to describe the particular form of obstruction suitable for such therapy. Cantor (6) states the use of the tube in postoperative ileus constitutes the type of case in which the results of intestinal intubation are most brilliant but the use of the long tube therapeutically in intestinal obstruction is exceedingly dangerous. Grimson and Hodge conclude a decompression by intestinal intubation and suction is an important therapeutic aid in the treatment of intestinal obstructions produced by multiple postoperative or inflammatory adhesions. Wangenstein (18) writes, "Trial with the method indicates that almost invariably incomplete simple adhesive obstructions whether of remote or recent origin may be satisfactorily dealt with by suction" and (suction) may be employed with advantage in a large number of obstructions of the small intestine in which the strangulating element is absent. Bockus is of the opinion that the tube finds its chief use in patients presenting adynamic ileus and those with simple mechanical obstructions particularly when this is due to adhesions and when distention has developed. Noer and Johnson have found it of value in their cases of so called occluded

Fig 5. a, left Mercury bag broke on withdrawal of tube, scattering 4 cubic centimeters of metallic mercury in small bowel. This film taken 8 hours after accident. b, right Ten days later shows minute globules of mercury still present. No clinical evidence of mercury poisoning

ileus and the only treatment necessary in non occluded cases

These few quotations have been given as a small example of the apparent contradictory indications for intubation. They show the necessity of simplifying and clarifying by a change in terminology the general type of case that is best treated by intestinal decompression. Pending standardization of terminology we believe that more frequent use of the term

small bowel distention will enable surgeons to visualize the type of patient in whom intubation is particularly indicated. Some patients suffering from medical conditions present severe distention. The problem confronting the surgeon is that of relieving distention which embarrasses circulation and respiration and which if not relieved may be an important factor leading to death. To argue whether distention represents dynamic or adynamic ileus alone, simple obstruction, mechanical obstruction or occlusive ileus or obstruction only adds confusion and delays the proper therapeutic approach. In small bowel distention due to causes other than strangulating obstruction intubation is definitely indicated as the first treatment and is often the only treatment necessary. When intubation does not relieve distention completely after a reasonable period of time then

surgery must be considered. In primary strangulating obstructions or obstructions of the colon with great distention of the large bowel it is obvious that surgery is urgently indicated and intubation should not be used as a temporizing agent. There has been no instance in our experience in which delayed operation due to the use of intubation has resulted in a fatality. We do recognize how ever this dangerous possibility and urge most careful observation of every patient being treated by intubation instead of surgery.

A few cases are briefly summarized to illustrate the principle of primary relief of small bowel distention by intubation alone.

CASE 7 (No 21530) W. L. male 46 entered the hospital on medical service with the diagnosis of acute ventricular tachycardia and heart failure. Severe and embarrassing abdominal distention developed. There were no abdominal scars and it is believed that the small bowel distention was due to edema of the mesentery or wall of the bowel due to heart failure. Intubation was advised and x ray taken 24 hours after introduction of 3 feet of Harris tube showed complete deflation of the distended loops. Total period of intubation was 6 days.

This case illustrates small bowel distention associated with heart failure and a successful therapeutic result by intubation alone.

CASE 8. (No 16410) S. G. female aged 42 entered the hospital March 3, 1946 complaining of

had not traversed the ileocecal valve. Such a complication proved to be of diagnostic value and was an indication for surgical interference even though there was clinical and radiological evidence of deflation (Case 6).

CASE 6 (No. 15536.) F G female, aged 37 entered the hospital August 11, 1946, with the diagnosis of acute perforative appendicitis and peritonitis. Operation the same day confirmed the diagnosis of generalized spreading peritonitis. Appendectomy was performed and the wound was closed without drainage. August 14, 1946, there was radiological and clinical evidence of small bowel obstruction (Fig. 4a). Harris tube was passed August 20, 1946, small bowel distention had been relieved. An attempt to remove the tube was unsuccessful (Fig. 4c) and it was decided to allow it to pass per rectum. Figure 4d shows a section of the cut tube lying in the small bowel and, by August 27, 1946, no further progress of it. Patient appeared clinically well but operative interference was indicated because of failure of cut Harris tube to move from its original position. At operation August 28, 1946, loops of small bowel were found in the pelvis bound down by plastic adhesions and dilated. The terminal loop of ileum 1½ feet proximal to the ileocecal valve was bound down in a V-shaped kink with a section of Harris tube located within the loop, one half of the bag in each arm of the V. Lysis of adhesions was performed, the bowel opened and the bag found inflated. Tube and bag were removed and a Witzel type enterostomy made from this small opening in the bowel. Postoperative course was uneventful.

Inability to withdraw the tube even though it had not passed through the ileocecal valve and failure of cut section of the Harris tube to pass were important diagnostic points. We were convinced this patient had a mechanical small bowel obstruction, incomplete but sufficiently severe to threaten catastrophe were it not relieved by surgical means. The osmotic swelling of the bag probably was a contributing factor in the failure of this section of tube to pass completely through the V-shaped kink in the terminal ileum.

BREAKAGE OF MERCURY BAG

In 4 cases the bag containing mercury ruptured during the process of removing the tube. In these careful study has been made to determine clinically and by laboratory means if there was any evidence of mercury absorption or poisoning. Urine examinations were repeatedly negative and at no time was there mercury toxicity. These findings have been

corroborated by other investigators (5) as well as by earlier experiments on dogs which the senior author performed before originally introducing the use of mercury as a vehicle for the bag of the Miller Abbott tube. The time necessary to empty the bowel of the free mercury present after rupture of the bag varied. In 1 patient (Fig. 5 a and b) mercury appeared in globules in the stools for approximately 6 days at the end of which time there was very little x ray evidence of any remaining in the bowel. It has never produced diarrhea. One action of mercury frequently noted is a black discoloration of the rubber bag apparently due to chemical interaction between the rubber and the mercury. We have noted no ill effects from this phenomenon.

INDICATIONS FOR INTUBATION THERAPY

Writers on the subject of intubation have tried to define accurately the type of case in which it is of therapeutic value. Considerable confusion exists because of the wide variety of terms used to describe the particular form of obstruction suitable for such therapy. Cantor (6) states, "the use of the tube in post-operative ileus constitutes the type of case in which the results of intestinal intubation are most brilliant but the use of the long tube therapeutically in intestinal obstruction is exceedingly dangerous." Grimson and Hodge conclude "a decompression by intestinal intubation and suction is an important therapeutic aid in the treatment of intestinal obstructions produced by multiple postoperative or inflammatory adhesions." Wangensteen (18) writes "Trial with the method indicates that almost invariably incomplete simple adhesive obstructions whether of remote or recent origin may be satisfactorily dealt with by suction and (suction) may be employed with advantage in a large number of obstructions of the small intestine in which the strangulating element is absent." Beckus is of the opinion that the tube finds its chief use in patients presenting adynamic ileus and those with simple mechanical obstructions particularly when this is due to adhesions, and when distention has developed. Noer and Johnson have found it of value in their cases of so called occluded

Fig 5 a, left Mercury bag broke on withdrawal of tube, scattering 4 cubic centimeters of metallic mercury in small bowel. This film taken 2 hours after accident. b right Ten days later shows minute globules of mercury still present. No clinical evidence of mercury poisoning

ileus and the only treatment necessary in non occluded cases.

These few quotations have been given as a small example of the apparent contradictory indications for intubation. They show the necessity of simplifying and clarifying by a change in terminology, the general type of case that is best treated by intestinal decompression. Pending standardization of terminology we believe that more frequent use of the term 'small bowel distention' will enable surgeons to visualize the type of patient in whom intubation is particularly indicated. Some patients suffering from medical conditions present severe distention. The problem confronting the surgeon is that of relieving distention which embarrasses circulation and respiration and which if not relieved may be an important factor leading to death. To argue whether distention represents dynamic or adynamic ileus, ileus alone, simple obstruction, mechanical obstruction or occlusive ileus or obstruction only adds confusion and delays the proper therapeutic approach. In small bowel distention due to causes other than strangulating obstruction intubation is definitely indicated as the first treatment and is often the only treatment necessary. When intubation does not relieve distention completely after a reasonable period of time then

surgery must be considered. In primary strangulating obstructions or obstructions of the colon with great distention of the large bowel, it is obvious that surgery is urgently indicated and intubation should not be used as a temporizing agent. There has been no instance in our experience in which delayed operation due to the use of intubation has resulted in a fatality. We do recognize however this dangerous possibility and urge most careful observation of every patient being treated by intubation instead of surgery.

A few cases are briefly summarized to illustrate the principle of primary relief of small bowel distention by intubation alone.

CASE 7 (No 21530) W L male 46 entered the hospital on medical service with the diagnosis of acute ventricular tachycardia and heart failure. Severe and embarrassing abdominal distention developed. There were no abdominal scars and it is believed that the small bowel distention was due to edema of the mesentery or wall of the bowel due to heart failure. Intubation was advised and x ray taken 24 hours after introduction of 3 feet of Harris tube showed complete deflation of the distended loops. Total period of intubation was 6 days.

This case illustrates small bowel distention associated with heart failure and a successful therapeutic result by intubation alone.

CASE 8 (No 16410) S G female, aged 42 entered the hospital March 3 1946 complaining of

Fig 6 Case 9. a, Mechanical small bowel obstruction. 60 year old female due to adhesions from hysterectomy performed at age 40. b, Eighteen hours later showing only partial deflation by Harris tube. Operation indicated. c,

Six days postoperative. Film shows complete relief of small bowel obstruction and distention by combination of operative lysis and postoperative suction. Gas present in large bowel. T. to be withdrawn 4 days later.

abdominal pains for the preceding 24 hours accompanied by distention, nausea and vomiting. Cholecystectomy and hysterectomy had been performed 1 year previously. Figure 2a taken on date of admission shows distention of multiple loops of small bowel. Harris tube was passed immediately. Nine hours after introduction the head of the tube had progressed rapidly to the obstructed small bowel but recheck film showed additional loops of small bowel distention despite successful intubation (Fig 2b). Clinically the patient appeared to be worse. Abdominal pain was increasing, and it was therefore decided that operation was indicated. Operation revealed mechanical small bowel obstruction due to an exudate encircling the lower jejunum and originating from a perforating acute mesenteric adenitis. Lysis of the obstructive adhesions was performed and the immediate postoperative course was satisfactory. Three days after surgery x ray examination showed no small bowel distention and as the patient was comfortable and objecting strenuously to the tube, it was removed before the usual therapeutic test of discontinuing suction for 24 hours was instituted. Symptoms immediately recurred and roentgenogram March 8, 1946 (Fig 2d) showed recurrent obstruction as evidenced by a considerable number of loops of distended small bowel. Subsequent intubation was successful and after 9 days the final film (Fig 2e) showed no evidence of small bowel distention. The tube was withdrawn and patient's recovery was uneventful.

This case illustrates continued increase in small bowel distention and abdominal pain despite suction intubation, which was rapid

Surgery was therefore indicated and was performed because of fear of early strangulating obstruction. Inflammatory exudate from a perforated mesenteric gland part of a generalized mesenteric adenitis was the cause of obstruction. The postoperative course was complicated by recurrence of small bowel distention which was successfully treated by intubation alone.

CASE 9 (No 16557) G B female, aged 60, entered the hospital March 14, 1946 with a 3 day history of epigastric pain, nausea, vomiting, and abdominal distention. Past history revealed similar less severe attacks over many years. Hysterectomy was performed at the age of 40. Examination showed a patient obviously dehydrated presenting marked abdominal distention (Fig 6a). Harris tube was passed. X ray examination showed tube in the obstructed bowel, but clinically and radiologically there was not sufficient relief of the obstruction to warrant continued treatment by intubation alone (Fig 6b). Operation revealed multiple adhesive bands with one strong band low in the pelvis acting as a "clothes line" type of sling over which a loop of ileum was partially strangulated. Lysis of adhesions was performed. Postoperatively there was continued evidence of some small bowel distention which was successfully treated by suction intubation (Fig 6c).

This case illustrates extreme small bowel distention which was unrelieved by intubation alone. Clinical and radiological evidence in

Fig. 7 Case 10 a, Small bowel mechanical obstruction 8 days postoperative to cesarean section and sterilization b, Five days after intubation, gas is seen in large bowel and

only occasional loop of distended small bowel visible. c, Eight days after intubation was started there is complete relief of obstruction clinically and radiologically. No operation

licated continuation of small bowel distention. Clinical condition further indicated beginning strangulating obstruction making surgical interference advisable.

CASE 10 (No 21690.) M R. female aged 34 tripara, entered the hospital February 4 1947 for cesarean section. Section and sterilization procedure were performed February 4 1947. On the 8th post operative day (February 12 1947) patient developed abdominal pains and pronounced abdominal distention. X ray examination showed evidence of mechanical small bowel obstruction probably due to a postoperative adhesive band (Fig 7a). Intubation was performed on this date and clinical improvement was noted within 12 hours. Five days after the Harris tube had been introduced x ray film showed an occasional loop of distended small bowel but most of the gas was seen in the large bowel (Fig 7b). Clinically and radiologically the patient was well. On the 8th day after intubation was started (February 20 1947) final x ray examination showed complete relief of obstruction and her clinical improvement confirmed this fact (Fig 7c). Tube was withdrawn February 21 1947 after 9 days of intubation.

This case illustrates acute postoperative distention of the small bowel which responded immediately and successfully to intubation. It is useless to argue whether this abnormal small bowel distention was due to 'adynamic or dynamic ileus to mechanical obstruction or simple adhesive obstruction'. In this patient distention was due to a postoperative adhesion which mechanically partially blocked the

small bowel and produced abnormal distention. Relief of distention permitted return of normal function and normal blood supply to the small bowel and yielded a complete and satisfactory therapeutic end result.

RESULTS

In this series of 100 cases of intestinal intubation there was complete relief without surgery of the small bowel distention or obstruction in 41 cases occurring in 37 patients. Two deaths occurred in this group both were in medical cases and were not related to intubation therapy. One case was that of a patient with uncontrolled ventricular tachycardia accompanied by severe small bowel distention. The distention was relieved completely by intubation 5 days before his death from heart failure. The second case was one of renal failure due to sulfonamide medication which was being treated by peritoneal irrigation according to the method of Fine and associates. Intubation was used for the relief of the paralytic small bowel distention, and death was due to perforation of a uremic ulcer of the stomach.

In the remaining 59 cases of intubation carried out on 49 patients this therapy was used in conjunction with surgery in 13 cases preoperatively and in 46 postoperatively. Thirteen deaths occurred in this group 8 were

due to advanced metastatic peritoneal carcinoma. Four were due to peritonitis secondary to a perforated viscus and 1 to strangulating obstruction with peritonitis.

SUMMARY AND CONCLUSIONS

1 A study was made of 100 cases of intubation of the small bowel in 86 patients presenting distention or obstruction or both. Further experiences with the single lumen mercury weighted intestinal tube are reported.

2 Complications were: oiling of the tube in the stomach failing to pass the pylorus; inability to withdraw the tube; osmotic swelling of the rubber bag containing mercury; and rupture of the bag.

3 To minimize such complications changes in the technique and shortening of the long intestinal tube from 9 to 6 feet and flushing the rubber bag containing mercury with carbon dioxide are recommended.

4 The accordion principle of intestinal pleating on the tubing is described. On this basis it is recommended that only 2 to 3 feet of tubing be passed beyond the pylorus as this length is sufficient to decompress the entire small bowel.

5 Treatment of small bowel distention by successful intestinal intubation is superior to operative enterostomy.

6 The principal indication for the use of intestinal intubation as a treatment is small bowel distention associated with simple adhesion obstructions or with certain medical conditions. It should never be used as a primary treatment for strangulating obstruction of the small bowel or in obstruction of the large bowel.

7 When intubation is used to relieve small bowel distention frequent flat films and close

clinical observation are necessary in order to detect a change from simple to strangulating obstruction.

8 A statistical summary of 100 cases of intestinal intubation showed that this type of therapy was sufficient to relieve the small bowel distention or obstruction in 41 cases without recourse to surgical intervention. In 59 cases some type of operative procedure was used as a primary form of therapy.

CHARACTERISTICS OF MIXED TUMORS OF THE PAROTID GLAND GROWING IN VITRO

BENEDICT V FAVATA, MD Rochester New York

THE histogenesis of mixed tumors of salivary glands is obscure. Cohnheim was the first to advance the theory that they were essentially epithelial. Several investigators have supported this concept (2, 5, 8, 9). They hold that the cartilage often present represents a change in epithelial components. Others believe that mixed tumors arise from pluripotent embryonal cells displaced during the course of development (4, 7, 10).

Murray has shown that neoplastic cells growing in vitro may evince some of the specialized characteristics of the normal cells from which they arise. Comparison of tissue cultures of parotid mixed tumors with cultures of duct cells from fetal parotid gland indicates that both grow in essentially the same patterns. This suggests that mixed tumors may be derived from cells lining the ducts of salivary glands.

Five sterile mixed tumors of the parotid gland were obtained at operation. The histological appearance of these neoplasms was almost identical. They were composed of clumps of small epithelial cells some of which formed small acini. The cell groups were separated from one another by masses of hyalin appearing faintly basophilic matrix in which were imbedded isolated cells larger than those seen in the epithelial clumps. This material appeared to be cartilage. All of the specimens also contained large quantities of edematous tissue rich in fibrils and stellate cells. The tissues cultured came from the immediate proximity of the sites from which blocks were taken for histological examination.

The method by which the tissues were grown in vitro involved the use of purified human fibrinogen and bovine thrombin. It

has been described previously in detail (6). The growing tissues were studied daily. Explants were made at appropriate intervals. Some cultures were fixed in Schaudinn's fluid and stained with hematoxylin and eosin.

The cultural characteristics of each of the five tumors were similar.

Only a few small macrophages migrated from the explants during the first week of their growth. Then long thin, spindle shaped cells with elongated nuclei and fine terminal processes appeared (Fig. 1). Their ends overlapped to form long strands. These cells, presumably fibroblasts, delineated other groups of cells or radiated from the periphery of the cultures. They were conspicuous only during the early period of growth and later became masked by the more actively proliferating epithelium.

Little isolated clumps of closely packed small ovoid cells with basophilic cytoplasm were seen near the periphery of the growing masses. Their cytoplasm became acidophilic and developed short irregular processes. These cells disappeared during the third week of growth despite vigorous mitotic activity. They were probably macrophages and resembled those that migrated early in the course of the cultures growth.

At the same time fibroblasts were first noted clumps of large rounded almost cuboidal cells with finely granular basophilic cytoplasm and centrally placed ovoid nuclei appeared. These large cells formed long cords and acini enclosing round spaces (Fig. 2). Later they grew in broad sheets in which the cells were evenly spaced giving the growth a mosaic pattern (Figs. 3 and 4). The cells at the growing edges of these sheets continued to form cords and acini. Some cells appeared distinctly columnar.

The large epithelial sheets gradually developed focal areas in which the cells had acidophilic cytoplasm appeared smaller and

were packed together more closely (Fig. 3). Cells intervening between the focal areas appeared to spread out their cytoplasm so that nuclei came to lie farther apart. Fine intercellular bridges could be detected. This pat-

tern was fully developed in cultures 60 days old.

During the next 30 days spaces appeared in the centers of some of the condensed foci (Fig. 6). The cells in these areas became smaller and

their cytoplasm appeared more acidophilic. Large vacuoles developed in the intervening cells. Some of these cells disappeared leaving

irregular spaces. Most of the cultures died within 140 days of the time they were started. Regressive changes dominated the picture during the last 6 weeks.

Tissue from the parotid gland of a 4 month old human fetus delivered by hysterotomy was grown in vitro using the same techniques. This tissue contained only ducts and no recognizable acinar components which develop during the fifth month of intrauterine life. The potentialities for the formation of acinar cells by this tissue are present. However it seems highly improbable that the stimuli afforded by tissue culture can evoke them. Differentiation is distinctly uncommon among most cells growing in vitro. It seems reasonable to assume that the epithelial elements contained in these explants of fetal parotid gland were derived solely from ducts.

Sheets of large rounded almost cuboidal cells with pale cytoplasm and centrally placed large round or ovoid nuclei were seen in cultures only 12 days old (Fig 7). Some of these cells were grouped about spaces. Others formed cords. Condensed foci of smaller acidophilic cells appeared. Large cytoplasmic vacuoles formed (Fig 8). Clear areas developed in the cell sheets. The development of these explants resembled closely that of the cultures made from mixed tumors. The embryonal cells grew less vigorously than the tumor cells. The total mass of cells formed by fetal parotid explants never approached that of explants derived from the mixed tumors. Good growth lasted for only 37 days as contrasted with the 90 days of progressive growth of the neoplastic cells.

This study suggests that the pleomorphism that characterizes mixed tumors of salivary glands may result from secondary changes in a neoplasm composed almost exclusively of epithelium. The solution of cells in actively

growing sheets may be due either to hypersecretory activity or more probably to some pathological mechanism resulting from adverse environmental circumstances. The culture is bathed in a fluid which may remove the products of cell disintegration but the growing tumor with its relatively poor blood supply to its interior must store these products as a gel which contains some viable appearing cells. The end result would approximate closely the appearance of cartilage or myxomatous tissue. It has long been known that these elements in mixed tumors of salivary glands do not provide the usual tinctorial reactions of cartilage or myxomatous tissue of unquestioned mesenchymal origin (12).

While these observations support those who adhere to the epithelial nature of mixed tumors they do not form any basis for discriminating between the embryonal or adult nature of the cell of origin. Mixed tumors comparable to those found in man have not yet been produced in lower animals. However as cancer research progresses, the argument that misplaced embryonal cells give rise to neoplasms becomes progressively more tenuous.

THE USE OF POLYTHENE FILM AS A DURAL SUBSTITUTE

An Experimental and Clinical Study

M HUNTER BROWN M.D., JOHN H GRINDLAY M.D., F.A.C.S. and
WINCHELL McK CRAIG M.D. F.A.C.S., Rochester Minnesota

INVESTIGATORS have long sought an adequate and practical substitute for the dura mater when replacement of this membrane is necessary by reason of injury or disease. An imposing list of materials has been subjected to experimental and clinical tests and then rejected as unsuitable or used with reluctance in the absence of a more satisfactory substance. At different times in the past the following groups of materials have been employed with variable success: (1) the metallic foils—gold, silver, platinum and more recently tantalum; (2) autoplasmic membrane—fascia lata, peritoneum, peritoneum and fat; (3) nonviable membrane—amniotic membrane, allantoic membrane and Carle membrane; (4) a group of miscellaneous materials including celluloid, cellophane, fibrin film, and rubber tissue. All but a few of the foregoing substances have been discarded entirely; the field of usefulness of the remainder has been so restricted by their inability to meet many of the criteria of a dural substitute that the search has still continued. In a previous communication (1) we presented a preliminary report on polythene film as a dural substitute; this paper is intended to complete in greater detail our present experimental and clinicopathologic knowledge of this material. Necessarily much still remains unsaid on this latest addition to plastics in surgery.

There is general agreement that dural substitutes should possess certain basic criteria as follows: (1) inertness in cerebral tissue; (2) nontoxicity; (3) nonresorbability; (4) high tensile strength; (5) elasticity; (6) suturability; (7) nonadherence to leptomeninges and cortex. It is implied in criteria 1 and 2 that the mate-

rial be nonpileptogenic and noncarcinogenic. In addition to these basic criteria it is advantageous for the substance to be available in free supply, relatively inexpensive and easily sterilized. The different criteria listed are necessary in different surgical situations and compound the problem of a substitute material beyond the mere repair of dura. In the case of cerebrospinal rhinorrhea or of an open ventricle following resection of a lobe the emphasis falls on tensile strength and suturability in order to construct a watertight dam. Nonadherence is the primary requisite of a dural substitute in cases of penetrating cranio-cerebral injuries. In the group of malignant gliomas resection is usually subtotal and recurrence may be anticipated; in this situation a dural substitute possessing some degree of elasticity would be desirable for purposes of decompression. All of these qualities are therefore desirable under the special conditions which are encountered in the everyday practice of neurologic surgery.

REVIEW OF OTHER SUBSTITUTE MATERIALS

The substitute materials which have attracted the most attention during the recent war period are animal membrane, tantalum foil and fibrin film. The remainder have been almost entirely discarded aside from the occasional use of fibroplastic substances such as fascia. In an extensive study of numerous viable and nonviable materials by Pudenz and Odom it was found that tantalum foil was far more effective than any of the animal membranes or polyvinyl alcohol from the standpoint of preventing meningocerebral adhesion. The various materials were placed in the subdural space of cats for periods up to 240 days; all were found to be encapsulated in varying degree. These authors found that the different animal membranes were resorbed and fu-

Presented in The Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, New York, September 8-11, 1947.

mon of the two layers of the capsule then occurred. There was an eventual inflammatory reaction binding brain and dura that was probably greater than if the animal membranes had not been used. The extent of adhesion varied somewhat with the degree of wrinkling and folding of the membrane. In our experience this is almost invariably the case when the material is employed at the operating table. The authors concluded that the use of animal membrane for the prevention of meningocerebral adhesions was no longer warranted. Other major drawbacks to the use of membrane particularly its low tensile strength and lack of suturability are well known.

Pudenz and Odom found that tantalum foil on the other hand, provoked only minimal reaction and there was but slight adhesion at the margins of the neomembrane. Delarue, Linell, and McKenzie placed tantalum foil under the dura of 12 dogs and described serious reactive thickening of the dura and arachnoid which they felt contraindicated its use. Robertson and Peacher however were unable to confirm this finding in a variety of clinical cases in which they used foil to prevent adhesion. They felt that it was of definite value for this purpose. These authors noted 2 cases in which crepitus developed postoperatively and they had some difficulty with wrinkling and folding of the foil. Sachs recently has warned against the use of foil as a dural substitute because of crepitus. Thin tantalum rattles with the slightest movement like a dry leaf in the wind thus noise recurring with every cerebral pulsation becomes extremely annoying to the patient. Sachs noted several instances in which the material had to be removed. The present status of tantalum foil may be summarized by stating its advantages to include inertness in tissue and nonadherence and its disadvantages to be the occurrence of crepitus, opacity to roentgen rays, low tear resistance and lack of suturability.

The major clinical and experimental investigations into the use of fibrin film as a dural substitute were carried out by Ingraham and Bailey and Ingraham, Bailey and Cobb. They established the fact that fibrin film is gradually absorbed and replaced by a neomembrane with minimal reaction of the surround-

ing tissues. In addition there was good evidence that the film was valuable in minimizing meningocerebral cicatrix. Ferry and Morrison and Morrison and Singer have studied the mechanical properties of fibrin films and their resorption rates in tissues. They emphasized the variation in tensile strength, elasticity and resorption time in films that differed in the proportions of fibrin and plasticizer. In rabbits the persistence time of fibrin film treated with a high proportion of plasticizer extended to more than 80 days whereas the purest fibrin product began to disintegrate as early as 5 days after implantation. Loss of tensile strength and elasticity was characteristic of the older films. In general therefore fibrin film may be appraised as unequivocally harmless when in contact with cerebral tissue, and of value in reducing traction on the brain by the extracerebral tissues. The film has drawbacks however that militate against its use as an all round dural substitute: difficult and highly expensive preparation and resorbability which is too rapid in the purest, and consequently most desirable film for purposes of repair and replacement of dura. Moreover it is deficient in suturability with a tensile strength that is not sufficient to maintain a watertight closure against pressure.

Thus the status of dural substitutes up to the present time has been that the necessity for repair entailed the use of materials that were either fibroplastic, laborious to prepare and handle or possessed properties that were not suited to meet the problem at hand. When polythene film became commercially available in quantity and appeared to have the desired physical qualities for a dural substitute experimental and clinical tests were carried out to determine its suitability.

PROPERTIES OF POLYTHENE

Polythene (polyethylene med-o-seal) is a synthetic, thermoplastic resin produced by the polymerizing of ethylene under conditions of high pressure and elevated temperature. The simplest chain polymer that can exist is formed—a belt of carbon atoms each one carrying two atoms of hydrogen to an approximate molecular weight of 18,000. By varying the molecular weight and the thickness of the

material, flexibility of this paraffinic hydrocarbon can be altered without the addition of objectionable plasticizers. Pure polythene may be injection molded into any thickness of film or size of tubing that is desired for the particular surgical use at hand.

Polythene is remarkable by virtue of its extreme chemical inertness. It is not substantially affected at room temperature by concentrated hydrochloric, sulfuric or even by hydrofluoric acid and resists concentrated sodium hydroxide. The plastic is insoluble in tissue fluids, extremely resistant to moisture and oxidation and has the anticoagulant property that characterizes paraffinic products when they are brought into contact with blood. The film employed as a dural substitute in these investigations is a waxy white translucent material tasteless and odorless 0.002 inch (0.005 cm) in thickness. Recently film of a thickness of 0.001 inch (0.0025 cm) has been obtained for clinical use. The film has great tensile strength and resistance to tearing permitting easy firm suturing. It is sufficiently elastic to allow an elongation up to 60 per cent when subjected to a stress of 1,200 to 1,400 pounds per square inch. Above this tension the cold-drawing phenomenon occurs which permits a further increase in tensile strength to as high as 25,000 pounds per square inch with some irreversible elongation of the material. Increase of temperature above 50 degrees C (122 degrees F) increases the flexibility of the specimen; the critical temperature is 115 degrees C (239 degrees F) above which polythene exists as an amorphous liquid. Throughout the range of body temperature variations the plastic has constant physical properties. Polythene film is not opaque to roentgen rays. The material will tolerate boiling but not autoclaving. We have found that cold sterilization according to the following method is the simplest way of preparing the film for surgical use: a soap and water wash immersion in 1:1,000 solution of merthiolate for 30 minutes followed by a rinse in isotonic saline solution.

From the standpoint of advantageous physical properties polythene film appeared to be suitable for a trial as artificial dura. While this work was in progress Ingraham, Alex-

ander and Matson in a review of plastic materials in surgery, referred to their unpublished studies in which polythene tubing was buried in the cerebral hemispheres of animals. A thin fibrous neomembrane formed about the tubing with no evidence of any irritative effects. Apart from this work no reference to the use of polythene in experimental neurosurgery exists to our knowledge.

EXPERIMENTAL STUDIES WITH POLYTHENE

Ten animals (8 dogs and 2 monkeys) were employed in the experimental study with polythene film and tubing. All operations were carried out with the animals under intra-tracheal ether anesthesia, sterile technique being used. In 7 animals large osteoplastic bone flaps were fashioned and a comparable area of dura was excised and replaced with polythene film. In addition in 2 of these animals the underlying cortex was lacerated, producing specific neurologic defects. In the 3 remaining animals polythene tubes were inserted into the lateral ventricle to form an artificial fistula between this cavity and the subarachnoid space. The brains of 8 animals have been re-examined at intervals of 2, 4, and 6 months; the others are being observed in definitely for possible late deleterious effects. The 10 animals used in the series all survived primary craniotomy. At the time of re-examination there were 2 postoperative deaths: one animal expired 2½ months after ventriculostomy and 4 animals were employed to obtain complete histologic studies. Wound healing was normal in all instances and there were no abnormal neurologic effects attributable to the polythene film or tubing. In the 2 instances in which the cortex was lacerated beneath the film, recovery of sensory motor function proceeded at the anticipated rate. The 3 ventriculostomy tubes have been re-examined and found to be patent, unchanged in appearance and containing spinal fluid. In 1 instance interventricular bleeding had occurred when the ventriculostomy tube was inserted, blocking the aqueduct of Sylvius; the tube effectively by-passed the block for 6 months and when it was removed the animal expired rapidly of acute obstructive hydrocephalus.

Fig. 1. Frontal section of brain of dog 5, 16 months. The dotted line indicates the position of the polythene film which is present. Neomembrane blends imperceptibly into normal dura.

Examination of the film at the time of reoperation or killing of the animal showed that it was identical with the material in its normal state. In all cases when the bone flap was uncovered the film was entirely nonadherent to the underlying leptomeninges and cerebral cortex. Grossly and histologically a thin sub-

dural neomembrane forms between the film and the arachnoid. Actually this neomembrane is a regeneration of the inner layer of the dura mater from the margins of the defect into the dead space. The collagenous fibrils of the newly formed dura are oriented in a direction that parallels the film. This neomembrane is likewise nonadherent and may be easily dissected off the underlying arachnoid in both the wounded and unwounded animals. There does not appear to be any tendency to meningeocerebral adhesion. Histologic sections have failed to reveal any foreign body giant cells or evidence of reaction in the pia arachnoid and cortex. Figures 1 through 6 illustrate these characteristic pathologic features.

CLINICAL APPLICATIONS OF POLYTHENE FILM

After completion of the laboratory observations a clinical study of polythene film was carried out on 20 patients. Although the number of cases is insufficient to draw other than tentative conclusions the results have been promising and have paralleled closely what one would anticipate from the experimental findings. In 8 patients there was extensive neoplastic invasion of the dura necessitating its sacrifice and replacement. 7 of these patients had large meningiomas and the eighth a fibrosarcoma involving brain dura, bone and temporal muscle. The film was likewise employed to repair the dural defect in cases of cerebrospinal rhinorrhea. In these cases clos-

Fig. 4. Neomembrane, and lacerated left meninges and cortex of brain of dog 5 at 4 months. The fibrils of the regenerated dura are oriented in a position which is parallel to the surface of the brain without adhesion to the wound. $\times 38$

ure may be effected by the use of polythene film without the tension which so frequently exists even when extensive mobilization of the dura has been carried out. After the film has been pinned at the margins a continuous suture should be employed about the circumference of the defect to insure watertight closure. It is possible that the use of polythene will allow these patients to be uniformly managed by the unilateral transfrontal approach thus avoiding the complete anosmia that is a sequela to the bilateral operation.

Apart from the primary purpose of polythene film in repair and replacement of dura subsidiary uses of considerable importance in neurologic surgery follow the logical application of its various properties. We have employed the film in the prevention of adhesion between the brain and the extracerebral structures in lobotomy. When the dura is split to permit insertion of a cutting instrument under direct vision in lobotomy there is usually considerable difficulty in the repair of this membrane. To avoid having the bone button rest directly on the cortex film may be quickly inserted as an interposition membrane. The prevention of cicatrix formation in penetrating head injuries is advanced only as a tentative application in lieu of sufficient personal experience; the experimental findings would indicate that polythene has interesting possibilities in this respect.

Fig. 5. Postmortem photograph of polythene film overlying a large lacerated wound in the motor and premotor areas. The regenerated dura has been turned back to illustrate the translucence and nonadherence of the film after 6 months *in situ*. Monkey 2.

The remaining clinical applications require no additional comment excepting the use of film in arresting bleeding by tamponade. When severe hemorrhage from a venous sinus and inaccessible vessel or a tumor bed can be controlled only with gauze packing a strip of film is interposed between the hemostatic agent (muscle fibrin foam or gelfoam) and the pack. The pack may be removed early in the postoperative period without fear of dis-

Fig. 6. Base of a large cortical laceration brain of monkey 2 at six months. The remaining cerebral debris is undergoing phagocytosis by glial cells; the cavity otherwise shows little reaction and a new limiting membrane has formed. $\times 13$

turbing the clot that has sealed off this bleeding point

Polythene is similar to silk nylon tantalum and other nonresorbable materials in that removal of the film is probably indicated if infection becomes established in a wound. Emphasis on strict aseptic precautions at the time of operation and in postoperative dressings is therefore essential. We have removed the film together with infected bone and bone wax in 2 cases of chronic sepsis. These cases illustrate points which are worthy of some discussion. In the first patient a *Micrococcus catarrhalis* infection followed transfrontal craniotomy. Removal of the film covering the anterior burr hole did not cause subsidence of the drainage; the bone was devitalized and eventually the flap was sacrificed whereupon drainage ceased. The second case was that of a large parasagittal meningioma in which a gauze pack was left in place for 7 days to control hemorrhage from a large communicating vein; in addition it was necessary to reoperate for a postoperative clot at which time the bleeding points in the bone flap required extensive coagulation and waxing. When the packing was removed infection developed in the tract and the bone flap became devitalized. Ten weeks after resection of the tumor the bone flap was removed and a large extradural abscess was evacuated. It was of interest to note that despite the degree of infection in this case the film was unchanged in appearance and physical properties, and was entirely nonadherent on removal. Dural regeneration was complete beneath the film and had effectively walled off the infection. It is likely that if no film or if a resorbable membrane had been used formation of an intracerebral abscess would have resulted. In the remaining

18 cases wound healing was normal and there have been no late complications in periods up to one year. There has been no single instance in the experimental or clinical series in which polythene film was responsible for drainage in a clean wound with an adequate blood supply.

SUMMARY

1. An experimental study of polythene film has shown that it fulfills the criteria of a dural substitute.
2. Polythene film does not adhere to the underlying leptomeninges and cerebral cortex. This property permits the dura to regenerate between the film and the arachnoid. Histologic studies indicate that there is no reaction in the pia arachnoid and cortex to the presence of the film.
3. A clinical trial of polythene film has shown that it is a satisfactory dural substitute and suggests other important uses of polythene in neurologic surgery.

EFFECTS OF ABSORBABLE FOREIGN SUBSTANCE ON BOWEL ANASTOMOSIS

HAROLD LAUFMAN M.D. F.A.C.S. and HAROLD METHOD M.D. Chicago Illinois

ABSORBABLE hemostatic materials represent a great advance in surgical hemostasis under certain emergent conditions. In addition to their ability to control most hemorrhages when properly used, these substances are absorbed with minimal reaction by most tissues. Frantz (4) has shown that in general oxidized cellulose does not delay healing of soft tissues. In clean bone surgery, however, its presence may slightly delay callus formation (7). Burns has demonstrated the pattern of absorption of oxidized cellulose from the uncontaminated peritoneal cavity. The substance is absorbed by phagocytosis with no ill effects. Jenkins and his group (5, 6) have pointed out that in the presence of contamination or infection in areas other than the peritoneum, the absorbable gelatin sponge may offer a culture medium which may influence the development and propagation of infection. It is not known to what extent absorbable hemostatic substances can be used safely in the peritoneal cavity when open surgery on the bowel is performed. The limitations of their use will depend to a great extent, on how they influence the spread of peritonitis and what effect they will have on the integrity of anastomoses and other sutured areas in the intestine.

Devine has shown that strips of peritoneum or skin applied about a bowel anastomosis will usually prevent peritoneal soiling from an otherwise inadequate suture line. While planning our experiments, the thought occurred to us that perhaps the absorbable hemostatic substances might also serve as sealing agents by virtue of their hemostatic qualities.

The purpose of our experiments then was to determine the limitations and extent of usefulness of the absorbable hemostatic substances

in intestinal surgery. Both the gelatin sponge and oxidized cellulose were used. We wished to determine whether the surgeon is justified in leaving such foreign substances in the peritoneal cavity after dealing with open bowel

EXPERIMENTAL PROCEDURES

In a group of preliminary procedures a strip of gelatin sponge was attached about an anastomosis of the upper ileum in which through and through sutures were used. All these dogs recovered without any ill effects. However, anastomoses in this area of the dog's intestine are known to heal without much difficulty almost regardless of technique used. We decided therefore to conduct a controlled experiment with anastomoses of the descending colon.

Ordinary mongrel dogs were starved for 24 hours prior to surgery, but were otherwise unprepared preoperatively. Intravenous nembutal anesthesia was used. Through a midline incision the colon was brought up and walled off with pads. A portion of the descending colon was kneaded free of its contents and cut across between rubber-tipped clamps. The field was walled off with sponges and open ends of bowel were carefully cleansed of fecal matter with gauze pellets. Instruments were discarded as they became contaminated. The standardized technique of anastomosis consisted in using only 8 interrupted inverting mattress stitches of fine silk through all layers. In the control group this was all that was done, and the abdomen was closed. This procedure carried with it a certain amount of risk, since the silk in traversing all the layers carried contamination to the serosal surface.

In a second group the ends of four alternate stitches were left long and a strip of gelatin sponge was applied around the bowel over the anastomotic line and tied in place by securing these ends (Fig. 1). In a third group the same procedure was done using a strip of oxidized cellulose. 2 brands of cellulose were used

Presented in The Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, New York, September 8-12, 1947.

Fig Technique of performing experimental open anastomosis of descending colon in unprepared dogs by 8 inverting interrupted mattress sutures of silk. Figures C, D and E show method of applying absorbable hemostatic substance around anastomotic line.

RESULTS

In a group of 8 control animals, 6 had successful anastomoses with no ill effects. One animal died 10 days postoperatively and at postmortem was found to have a small localized abscess in the vicinity of the anastomosis and milary abscesses in the lungs. There was no generalized peritonitis. One animal died 5 days postoperatively following a small disruption in the anastomosis and a localized peritonitis. The 6 surviving animals were sacrificed at various periods postoperatively ranging from 12 to 43 days. Except for the adherence of the omentum to a portion of the anastomosis there was no evidence of severe peritoneal infection (Figs. 2 and 3).

In 5 dogs gelatin sponge was placed about the anastomosis and held in position by the technique described. Of these dogs, 4 died 4 to 11 days postoperatively of a fulminating

peritonitis, and the anastomosis was found disrupted in each instance (Figs. 4 and 5). The remaining dog was explored 12 days postoperatively. The degree of adhesion formation about the anastomosis served as evidence of a severe, but healed peritonitis.

In 8 dogs a strip of oxidized cellulose was applied about the anastomosis in the manner described. Of these, 5 died 3 to 4 days postoperatively with disrupted anastomoses and generalized peritonitis (Fig. 6). Two of the remaining dogs in this series were explored on the fourteenth postoperative day after a severe postoperative course. In both instances the abdomen was found to contain a great deal of clear fluid, and the omentum and neighboring intestinal loops were plastered against the anastomosis. This was evidence of healing severe peritonitis. One dog in this series survived with no apparent ill effects and, when

Fig 5. Dog 4, gelatin sponge group. Specimen of anastomosis of descending colon at death 5 days after operation, showing disruption of anastomotic line.

Fig 6. Dog 12 oxidized cellulose group. Disruption of anastomotic line as seen at death 4 days following the operation. Specimen cut open. Arrow points to site of disruption.

Fig 7. Dog 22 oxidized cellulose group. Specimen of anastomosis of descending colon 14 days after operation showing severe peritoneal reaction and adhesion formation about anastomotic line despite successful result.

explored on the fourteenth postoperative day was found to have a clean abdomen except that the omentum was bound down to the entire circumference of the anastomosis (Fig 7).

In 4 dogs a second brand of oxidized cellulose was used. All died 3 days later from disruption of the anastomosis and peritonitis.

In summary 6 of 8 unprepared dogs in which open anastomosis of the descending colon was performed survived with no ill effects. Of 17 dogs in which an absorbable hemostatic substance was applied about the anastomosis (5 gelatin sponge 12 oxidized cellulose) 13 died of disruption of the anastomosis and peri-

remove these materials before closing the peritoneum or resort to other means of hemostasis.

TOXEMIA SUPERIMPOSED UPON PREPREGNANT HYPERTENSION TREATED BY SPLANCHNICECTOMY

MAX M PEET M.D. F.A.C.S. Ann Arbor Michigan EMIL M. ISBERG M.D.
Miami Beach, Florida, and ROBERT C BASSETT M.D., Ann Arbor Michigan

IT is generally recognized that the occurrence of pregnancy in a female who already has an established hypertension presents a complication with serious potentialities. In the first place 50 per cent of prepregnant hypertensives can be expected to develop a superimposed toxemia according to Dexter and Weiss. Secondly approximately one-quarter of these patients are left with higher blood pressure levels and more extensive disease as a result of a toxemic pregnancy. Thirdly the fetal mortality is greater in females with pre-existing essential hypertension (21 per cent in the series of Dieckmann and Brown). Furthermore organs weakened by pre-existing hypertensive disease are more susceptible to stress induced by toxemia than are healthy organs and therefore a greater incidence of cardiac failure renal insufficiency and cerebral accidents can be anticipated.

For these reasons many observers of this problem consider hypertensive cardiovascular disease a strong indication for the interruption of pregnancy. Certainly conservatism is warranted in any advice offered the hypertensive female who is desirous of a pregnancy yet she need not be completely discouraged from any attempt at childbearing provided she understands the potentialities and will cooperate in a cautious supervision of the pregnancy by her obstetrician.

Half of these hypertensive females are capable of going through a pregnancy without any aggravation of their hypertensive state. As for the other half close surveillance should enable prompt recognition of the development of toxemia. The pregnancy may be terminated should the toxemia persist. However another alternative is available and is herewith presented.

A new therapeutic approach to the problem of toxemia superimposed on prepregnant hypertension has been tried at the University Hospital during the past 5 years. Bilateral supradiaphragmatic splanchnicectomy with lower dorsal sympathetic ganglionectomy has been performed in 5 such cases. This surgical treatment is aimed directly at the underlying hypertensive disease for it is believed that the complicating toxemia is a consequence of the pre-existing hypertensive state.

In 2 of the patients so treated the results have been brilliant, following operation in both the toxemia disappeared normal blood pressure levels were achieved living infants were obtained and normal blood pressures have persisted for 4 years and 2 years respectively since delivery. In the remaining 3 cases the operation exerted no influence on the toxemia but in 2 of the cases the blood pressure levels following delivery have been significantly decreased as compared to the prepregnant level. In the fifth case splanchnicectomy in no way deterred the hypertensive

Fig. 1. Case 1 followed 4 years after splanchnicectomy

disease from pursuing a progressive and fatal course 14 months after miscarriage

CASE REPORTS

CASE 1. M P, age 31 years, secundigravida, was admitted on January 17, 1943, with the history that she had been refused life insurance at the age of 30 because of elevated blood pressure. During the prior 3 years she had noted progressive increase in severity of occipital headaches, fatigability and nervousness. She had moderate exertional dyspnea. One year previously she had completed her first pregnancy giving birth to a normal male infant. During this pregnancy she had albuminuria, and her blood pressure was in the range of 180 systolic and 110 diastolic; these levels persisted postpartum.

Her last menstrual flow began on September 6, 1942, and she was starting the second trimester of her second pregnancy. During the previous 3 weeks her headaches had become incapacitatingly severe, and her blood pressure had risen to an average of 205 systolic and 130 diastolic. Fundus examination revealed a grade III hypertensive retinitis with the arterioles showing generalized attenuation, localized angiospasm, arteriovenous notching, and increase in reflex stripe; there were several small granular hemorrhages and several cotton-wool patches. Both lung fields were clear. The heart was slightly enlarged, but otherwise not abnormal. The uterine fundus was felt above the symphysis pubis. There was no peripheral edema. Examination revealed a uterus compatible with a 4 months pregnancy.

The electrocardiogram was normal. The teleroentgenogram revealed slight cardiac enlargement, with the measurements for area and transverse diameter respectively giving variation values of +33 per cent and +6 per cent greater than predicted

normal. Retrograde cystograms were negative. The urea clearance averaged 71 per cent of normal. Maximum urine concentration on an 18 hour test was 1,017. Blood nonprotein nitrogen was 29.8 milligrams per cent. Urinalysis revealed 2+ albuminuria, and was normal otherwise.

Bilateral supradiaphragmatic splanchnicectomy with lower dorsal sympathetic ganglionectomy (9th through 12th dorsal) was performed on January 21, 1943. The postoperative course was entirely uneventful, and she was discharged on the 14th day with a blood pressure of 124/82.

She returned to the care of her obstetrician in Lawrence, Kansas, and for the remainder of her pregnancy her blood pressure remained within normal limits; the highest level reached was 132/90 shortly before delivery. The albuminuria persisted, but she was completely relieved of her severe headaches. On June 14, 1943, she was delivered of a full term normal infant by cesarean section.

Examination on August 11, 1947, four and one-half years after operation, found her in good health. Repeated blood pressure determinations averaged 116 systolic and 84 diastolic. She was completely relieved of her preoperative symptoms, and she was employed as a hospital maid in addition to keeping house for her two children. Fundus examination revealed only mild sclerosis of retinal arterioles. Both lung fields were clear and the heart revealed nothing unusual. Her electrocardiogram was normal. Teleroentgenogram revealed a definite decrease in cardiac size to normal as compared with the preoperative film; the values for area and transverse diameter respectively were now +0.1 per cent and +5.2 per cent greater than predicted normal. The urea clearance averaged 73 per cent, and the maximum urine concentration on an 18 hour test was 1,017. Urinalysis revealed 2+ albuminuria.

Fig. 3. Case 3, followed 3 months after splanchnicectomy

nervousness irritability tinnitus and fatigability progressively increased until June 1946 when she was studied in this hospital. She was then in the 4th month of her first pregnancy and during the previous month her headaches had increased markedly in severity and her blood pressure had risen appreciably.

On physical examination her blood pressure averaged 22 systolic and 130 diastolic in both arms, reclining. Fundus examination revealed marked generalized attenuation of arterioles, arteriovenous nicking and localized angiospasm. Both lung fields were clear. The heart showed nothing unusual. The uterine fundus was felt just above the symphysis pubis. There was no peripheral edema.

Intravenous pyelograms were normal. Blood non protein nitrogen was 24 milligrams per cent. Urea clearance was 95 per cent and 75 per cent of normal. Maximum specific gravity on an 18 hour concentration test was 1.024. Urinalysis revealed 1+ albuminuria. The electrocardiogram showed left axis deviation with normal T waves. Heart size was normal by teleoroentgenogram.

A bilateral supradiaphragmatic splanchnicectomy with lower dorsal sympathetic ganglionectomy (8th through 12th dorsal) was performed on June 7, 1946. Convalescence was uneventful and she was discharged on the 11th day.

Through the remainder of the pregnancy her blood pressure levels ranged from 130 to 180 systolic and 90 to 120 diastolic. On October 18, 1946 she was delivered of a normal female infant by cesarean section at another hospital. Her headaches were only partly relieved, and toward the end of the pregnancy she became edematous and showed a marked albuminuria.

She was examined in September 1947, almost 1 year after delivery and her blood pressure averaged 84/116. She was completely relieved of her preoperative headaches, but she still had ease of fatig-

ability. Her electrocardiogram was unchanged, and her cardiac size was still normal by teleoroentgenogram. Urea clearance and 18 hour concentration tests gave values indicating moderate impairment of renal function.

CASE 4. L. N. age 22 years, tertigravida was first discovered to have elevated blood pressure at the age of 18 during her first pregnancy which was interrupted during the second trimester because of a severe toxemia. The elevated blood pressure persisted postpartum. At the age of 20 her second pregnancy was interrupted at the end of the third month because of recurrence of toxemia. She entered this hospital in January 1944, in her third pregnancy complaining of severe headaches and impaired vision of 3 weeks duration.

On physical examination her blood pressure averaged 258 systolic and 170 diastolic. Fundus examination revealed normal optic discs, generalized narrowing of arterioles, and localized angiospasm; throughout both fundi there were small areas of pigment deposit and punctate hemorrhages. Both lung fields were clear. A systolic murmur was heard over the entire precordium. The uterine fundus was felt at the level of the symphysis pubis. There was no edema.

The intravenous pyelogram was normal, 1+ albuminuria was present. Maximum specific gravity on an 18 hour concentration test was fixed at 1.010. Urea clearance was 40 per cent and 36 per cent of normal. Blood nonprotein nitrogen was 38.5 milligrams per cent. The electrocardiogram was within normal limits, and the heart was borderline in size by teleoroentgenogram.

Bilateral supradiaphragmatic splanchnicectomy with lower dorsal sympathetic ganglionectomy (9th through 12th dorsal) was performed on February 3, 1944. Convalescence was uneventful and she was discharged on the 13th day to the care of her local

Fig. 4. Case 4, followed 13 months after splanchnicectomy

Fig. 5. Case 5 followed 57 months after splanchnicectomy

obstetrician. Her blood pressure persisted at 150/90 after operation. She had a spontaneous miscarriage on March 7 1944. In August 1944 her blood pressure began to rise, and on September 15 1944 she sustained a cerebral accident with right facial paresis. Her blood pressure levels then remained in the range of 200 to 220 systolic, and 100 to 120 diastolic. On May 23 1945 she died within an hour after a severe cerebral hemorrhage.

CASE 5 P C age 25 years, quadrigravida was first discovered to have hypertension 4 years previously in 1941 during her first pregnancy, which aborted spontaneously during the 5th month. The

elevated blood pressure persisted postpartum at an average level of 185/120. In 1942 she miscarried during the 5th month of her second pregnancy. Impaired vision and marked elevation of blood pressure had occurred. In 1943 she miscarried during the 7th month and again she had noted impaired vision. She was admitted to this hospital on May 21 1945 during the 5th month of her 4th pregnancy complaining of progressively increasing severe headaches puffiness of her face and blurred vision.

On physical examination her blood pressure averaged 200 systolic and 124 diastolic. Fundoscopic examination revealed moderate sclerosis and minimal

attenuation of arterioles, but no definite angiospasm. Both lung fields were clear and a loud systolic blow was heard over the whole precordium. The uterine fundus was almost at the level of the umbilicus. There was 2+ peripheral edema.

Intra-venous pyelogram revealed a minimal hydro-nephrosis of the right kidney and a normal left kidney. There was 2+ albuminuria. Maximum specific gravity on an 18 hour concentration test was 1.020 (moderate impairment). Urea clearance was 100 per cent and 108 per cent of average normal. Blood nonprotein nitrogen was 37 milligrams per cent. Teleoroentgenogram revealed moderate cardiac enlargement, the electrocardiogram showed QRS deflections of large voltage suggesting cardiac enlargement.

Bilateral supradiaphragmatic splanchnicectomy with lower dorsal sympathetic ganglionectomy (9th through 12th dorsal) was performed on May 28, 1945. There was no postoperative complication. She was then followed closely in the antenatal clinic and no reduction in blood pressure occurred. Toward the end of June 1945 her blood pressure gradually began to rise reaching an average level of 210/130 albuminuria progressively increased to 4+ urea clearance values diminished and marked angiospastic progression occurred in her eyegrounds. It was then decided to terminate the pregnancy medical induction of labor was carried out on July 10, 1945 and a stillborn fetus was delivered. Two weeks postpartum her blood pressure was 155/110.

Two years later in August 1947 her blood pressure levels averaged 164/106. She had no hypertensive symptoms, and she was doing the work of a farmer's wife.

ANALYSIS OF CASES

All 5 patients had prepregnant hypertensive disease and in each a toxemia occurred with pregnancy as manifested by exacerbation of hypertensive symptoms and rising blood pressure levels. Each patient in Cases 1 and 2 in which the results have been gratifying had hypertensive heart disease confirmed by teleoroentgenograms revealing cardiac enlargement and each showed evidences of impaired renal function yet their response to splanchnicectomy was dramatic. With the maintenance of normal blood pressure levels heart size in each decreased to normal on teleoroentgenogram.

In Case 3 the patient whose hypertensive disease had not yet progressed to cardiac involvement or impaired kidney function did not respond to sympathectomy her toxemia persisted until her uterus was emptied by cesarean section. She did give birth to a living infant.

In Case 4 the patient had marked impairment of renal function as evidenced by the fixed specific gravity of the urine and by the urea clearance values of 40 per cent and 36 per cent of average normal. Very little is to be expected from splanchnicectomy in patients with such marked kidney involvement. The operation was performed in the hope of aiding a patient to attain her extreme desire in giving birth to a living infant. In view of the fatal outcome 14 months after miscarriage, it is apparent that it is a mistake to do anything but interrupt a toxemic pregnancy promptly when findings of marked impairment of kidney function are present.

DISCUSSION

The therapeutic procedure of splanchnicectomy should be considered in cases of toxemic pregnancy superimposed on pre-existing hypertension before decision to interrupt the pregnancy is reached. The surgical treatment of hypertension not only affords an opportunity for relief from the toxemia and a good chance to obtain a living infant but it also presents the significant possibility of gaining a lasting relief from the underlying hypertensive state.

This forthright approach to the problem can be rationalized. The specific mechanism by which a toxemia of pregnancy is produced is not known nevertheless most investigators of this enigma consider the placenta to be the likely primary seat of the disorder. Pre-existing hypertension is one of a number of factors capable of disturbing the local circulation of the placenta, and thereby altering its hormonal activity. Hypertensive vascular disease is thus recognized as an important predisposing factor to the development of toxemia.

Splanchnicectomy has been found capable of arresting and reversing the course of hypertensive disease in some cases (6) this operation can thus be applied to this specialized problem for it may effect a reversal of the underlying hypertensive state and thereby remove the factor predisposing the toxemia.

The late vascular effects of a toxemic pregnancy have been shown by Golden, Dexter and Weiss to be directly dependent upon the duration of the toxemia, and they have pointed out that such effects may be prevented by

interrupting the pregnancy before the toxemia has persisted more than 3 weeks. Peckham found termination of pregnancy advisable in order to avoid chronic damage when signs and symptoms of toxemia persisted after 4 weeks of observation and treatment. These conclusions must not be disregarded in the management of patients treated by splanchnicectomy if the toxemia does not subside and disappear within 3 weeks following sympathectomy the pregnancy should be terminated.

Newell and Smithwick have reported a case of a patient with prepregnant hypertension upon whom lumbodorsal splanchnicectomy was performed during the first trimester. The two stage operation was done in July 1944 and the result was excellent. She maintained normal blood pressure levels for the remainder of the pregnancy and postpartum. This patient did not have a superimposed toxemia.

This treatment which utilizes splanchnicectomy is far from the complete answer to the serious problem of the prepregnant hypertensive with superimposed toxemia. However splanchnic resection may be used with reasonable hope in patients who are desirous of completing a pregnancy and whose kidney function is relatively good for some patients will respond dramatically. Unfortunately a method for determining beforehand which hypertensive patients will obtain a brilliant result from splanchnicectomy is unavailable at the present writing.

A study (7) of previously hypertensive females who experienced pregnancies subsequent to splanchnicectomy has led us to conclude that the young hypertensive female who

desires a pregnancy would do well by first having her essential hypertension treated by splanchnicectomy. If she maintains normal blood pressure levels for 1 year following operation she may attempt a pregnancy and be assured that she is reasonably protected against harmful late vascular effects and that her chances are excellent for giving birth to a normal infant.

SUMMARY

1 Splanchnicectomy has been performed in 5 cases of toxemia superimposed on prepregnant hypertension.

2 In 2 cases the results have been excellent, following operation in both, the toxemia disappeared, normal blood pressure levels were achieved living infants were obtained and normal blood pressures have persisted since delivery.

3 In the remaining 3 patients the operation exerted no influence on the toxemia but in 1 of the patients the blood pressure levels following delivery have been significantly decreased as compared to the prepregnant levels.

A CLINICAL STUDY OF THE EFFECT OF INTERCOSTAL NERVE BLOCK WITH NUPERCAINE IN OIL FOLLOWING UPPER ABDOMINAL SURGERY

ROBERT S. McCLEERY M.D., F.A.C.S., ROBERT ZOLLINGER, M.D. F.A.C.S. and
NORRIS E. LENAHEAN M.D., Columbus, Ohio

THE purpose of this investigation was to study further the procedure of intercostal nerve injection in 50 patients in order to evaluate its efficacy in reducing postoperative discomfort and pulmonary complications following upper abdominal surgery. The use of local anesthetics in a water base probably produces analgesia of too short duration and the use of preparations in oil and benzyl alcohol may result in the development of intercostal neuritis. Consequently a mixture of 1:1000 nupercaine in peanut oil was prepared and was used throughout the course of this study. We wished to ascertain whether such a preparation would give sufficiently prolonged analgesia without undesirable side effects. Pulmonary complications and postoperative pain are still vital problems to the surgeon especially following upper abdominal procedures, and any ancillary measures that can be directed to their prevention would be worth while.

The general improvement in operative mortality in the last decade has been due, to a large extent to the attention given the multiple details of preoperative and postoperative care. Despite the decrease in the problems of sepsis as a result of chemotherapy the incidence of postoperative pneumonia, atelectasis and venous thrombosis remains high. These complications now constitute the majority of the difficulties to which the patient operated upon falls heir. The exponents of early ambulation (13) have tended to show a decreased incidence of these complications attendant on the use of that regimen. Early

ambulation unquestionably offers many real benefits to the patient. However the practical application of it to the individual is often hampered by the discomfort of motion or by the sedation or narcosis applied for its amelioration. In spite of a general improvement in the various aspects of postoperative care, the constant factor of pain is with few exceptions, being controlled in the same manner today as in the past. If the disadvantage of narcotic administration lay only in the necessity for frequent application there would be little stimulus for changing present methods. However it is felt by many that there might be causal relationship between the control of pain by narcotics and the etiology of pulmonary complications.

Brock has outlined the factors influencing the incidence of postoperative pulmonary complications as follows (a) adequacy of preoperative prophylaxis (b) the type of operation with its possible sequelae of distention, peritonitis and diaphragmatic splinting (c) type and duration of anesthesia, (d) general condition of the patient, (e) sex and (f) season of the year. Most of the factors enumerated by Brock are either beyond the control of the surgeon or can be minimized by judicious preparation of the patient. However when operating to remove a disease process in the upper abdomen the surgeon is forced to accept the added responsibility of the high incidence of pulmonary complications in this area.

Cutler and Hoerr have stated that the type and duration of anesthesia are of secondary importance to the site of operation and the general condition of the patient. It is generally agreed that the highest incidence of pulmonary complications occurs following upper abdominal procedures. This adds to the mortality of an already formidable procedure, and

From the Department of Surgery, The Ohio State University and the Surgical Service, Culverdy Hospital. This study was supported by grant from the Conly-Coleman Fund for Surgical Research.

Presented in the Forum on Fundamental Surgical Problems before the Clinical Courses of the American College of Surgeons, New York, September 8-12, 1947.

presents a great challenge for study of the possible cause and prevention of pulmonary complications.

The pulmonary complications that endanger life or prolong morbidity are atelectasis and pneumonia. According to one theory it is felt that patchy or lobular atelectasis occurs first, and is either alleviated or goes on to bronchopneumonia. It is a well recognized clinical observation that the decrease in respiratory excursions following upper abdominal surgery can lead to the conditions that favor the occurrence of atelectasis. This depression of respiratory excursion is intimately associated with pain from the operative incision and many methods have been employed in an attempt to reduce this postoperative discomfort. Thus, tight abdominal binders and narcotics are used to decrease pain of motion and coughing. Since the abdominal muscles are active in respiration, there is a reluctance to take deep breaths because of the associated pain. Control of pain by narcotics, bed rest and tight dressings is a mixed blessing to the patient, however, since they reduce the tendency for activity, reduce the cough reflex and favor accumulation of bronchial secretion. Given these conditions, the occurrence of atelectasis will be frequent.

The effect of pain stimuli arising in the incision has been studied by Patey. By preoperative and postoperative x ray comparisons, he demonstrated a marked reduction of diaphragmatic excursion following abdominal surgery. He further states that deep breathing exercises were of little avail because of the splinting of the abdominal wall and that narcotics made the motion of the diaphragm more sluggish.

Kahn has shown by his experiments with dogs that stimulation of the central end of any intercostal nerve or of its branches to the abdominal muscles, causes a reflex inhibition of respiration. This reflex to the diaphragm was not abolished unless all of the lower intercostal nerves were sectioned.

Starr and Gilman state that expansion of the lower lobes closely follows the motion of the sixth through the tenth ribs and their attached muscles. These muscles are coordinated with the diaphragm and are its antago-

nists. Therefore, spasm in the flat abdominal muscles will prevent full diaphragmatic excursions as well as motion of the lower ribs.

In the past, several plans for controlling pain from the incision have been tested, and include Capelle's method of continuous infiltration of the abdominal wall with novocain. Crile's injection of the abdominal wall about the wound with quinine and urea hydrochloride, and the blocking of the intercostal nerves with various agents. Only the latter has received any widespread study and appears to have the least deleterious effects for the result accomplished. The effectiveness of such blocks has been measured by the decrease in the amount of narcotics needed to control pain and by the changes in vital capacity. The use of the former as a basis of judgment is known to be less accurate because of the variation in individual pain tolerance and because narcotics are often given on orders to give when necessary for the relief of restlessness or to produce sleep. Although the study of vital capacity is also subject to error it is a simple and objective test and is much more reliable.

There is ample evidence attesting the consistency and extent of the drop in vital capacity following upper abdominal surgery. Churchill and McNeil found that the percentage of preoperative vital capacity present 24 hours postoperatively was 25 per cent, while Powers recorded an average of 33 per cent and Beecher 42 per cent. All speak of the greatly increased drop in the upper abdominal cases as compared with those in the lower abdomen.

That intercostal block can reduce the amount of narcotics and the decrease in vital capacity following upper abdominal surgery has been supported by various investigators. Gius performed paravertebral intercostal nerve blocks with novocain on 2 patients with atelectasis. He observed a relief of pain and that the patients were able to cough freely and raise mucus plugs resulting in cure of the atelectasis. One of us (18) studied 15 cases by injecting the sixth to the eleventh intercostal nerves in the midaxillary line with eucupine in oil containing benzyl alcohol and demonstrated a definite reduction in the expected postoperative drop in vital capacity. Starr and Gilman used a eucupine-novocain mixture

Fig. 1 Average block, o—o— median block — — average control, oooooo median control

Fig. 2

Narcotic requirements All postoperative orders were written to include an order for morphine or other narcotic, every four hours if necessary for the control of pain. The decision as to the necessity for its administration was left to the nurse working with the case. They were not informed as to which cases had been injected and a comparison of narcotic usage in the two series should be valid on this point at least.

Pulmonary complications Those cases were counted as pulmonary complications when the course of patient's recovery was impeded by changes in the respiratory system. All patients were not routinely examined by x ray postoperatively. The usual clinical signs and symptoms were relied upon as indication for x ray examination. In general when there was an unexplained temperature elevation, questionable physical signs, respirations greater than 28 per minute, cough, pain in the chest, or cyanosis an x ray film of the chest was obtained for confirmation of atelectasis or pneumonia.

RESULTS

Vital capacity The well demonstrated drop in vital capacity on the first postoperative day has been previously mentioned and is in the range of 25 to 42 per cent of the preoperative level in different series. In our control series the average first day postoperative

vital capacity was 37 per cent of the preoperative level and the median was 36 per cent (Fig. 1). In opposition to these series Leithauser, employing early ambulation, has reported 7 patients having a vital capacity of 48 to 85 per cent on the first postoperative day following biliary surgery. Our control group was given the benefit of early ambulation and isolated cases in this group often fell within the range mentioned by Leithauser. In the larger group, however, such a high average is not maintained.

Figure 1 also shows that the injected series has an average and a median of 53 per cent of preoperative vital capacity at the end of 24 hours compared with 36 or 37 per cent in the controls. It is also noticeable that this order of difference is maintained throughout the first 4 days at least, and the control group does not approach the experimental at any point. Roughly patients in the blocked group reach a certain vital capacity 48 hours before the controls, i.e. experimental, 53 per cent on the first postoperative day; controls, 53 per cent on the third postoperative day.

Figure 2 is a graphic expression of the same data from a different standpoint. It will be seen that at the end of 24 hours postoperatively 54 per cent of the block series have more than 50 per cent of preoperative vital capacity, as against only 6 per cent of the controls.

TABLE II.—PULMONARY COMPLICATIONS

	Control	Block
Median age	46	45
Sex—per cent		
Male	40	58
Female	60	42
Pulmonary complications—per cent	13	6
Routine penicillin—per cent	37	20

speak a failure of the block is suggested by an average of 50 per cent vital capacity at 24 hours in those patients needing as many or more hypodermic injections than the average control

Pulmonary complications The same policy of early ambulation was applied to the control and blocked series and closely followed the first day ambulation plan of Leithauser

The difference between the sexes in the incidence of pulmonary complications is marked, as Cutler and Hoerr have shown an approximate 2 to 1 ratio of males to females. Blodgett and Beattie an incidence of 14.2 per cent in males and 5 per cent in females and Beecher a 3 to 1 preponderance in males.

That upper abdominal operations in themselves carry a very high incidence of pulmonary complications is suggested by Cutler and Hoerr's finding of an 11 per cent incidence in biliary tract procedures and 23 per cent in operations upon the stomach by Murphy who found 29 lobular and lobar atelectases of varying degrees in 100 gastrectomies and by Blodgett and Beattie who found 11 per cent pulmonary complications in first day risers and 13 per cent in nonearly risers following upper abdominal procedures. The figures of Murphy and of Cutler and Hoerr show a higher incidence after gastric procedures than in other upper abdominal surgery.

There is general agreement that advanced age with its attendant physical deterioration leads to a greater incidence of pulmonary complications.

A study of Table II shows that the 13 per cent incidence of pulmonary complications in the control, although the series is small, agrees well with the findings of larger series. The median age of the two groups are close enough to be disregarded. The preponderance of males and the routine use of penicillin postoperatively in only 20 per cent of the block series versus 37 per cent of the control

TABLE III.—OPERATIVE PROCEDURES

	Control	Block
1 Biliary tract.	15	15

group does not detract from the significance of the reduction to 6 per cent pulmonary complications in the experimental group. In addition Table III shows that 40 per cent of the procedures in the block group were upon the stomach, compared to but 33 per cent in the controls. Another interesting fact is that all pulmonary complications in both groups occurred following gastric surgery. Admittedly the difference between 6 and 13 per cent in a series of this size is not of statistical significance. However as mentioned above with all the factors tending to produce an increased incidence of pulmonary complications, 'stacked,' as it were against the experimental series, the difference may be real.

SEQUELAE OF PROCEDURE

In the hospital In no instance did a sterile abscess or infection develop in the thoracic wall from the presence of the oil.

In no instance did we observe a pleural type pain or pleural effusion from the procedure.

There were no cases of wound evisceration connected with the decrease of abdominal wall sensitivity.

As previously mentioned, two pneumothoraces did occur and must always be kept in mind.

After discharge Of the 40 cases blocked up to 2 months ago 33 have been followed. Twenty two were reached personally and 11 by questionnaire. There has been no instance of abdominal or thoracic pain suggestive of an intercostal neuritis.

DISCUSSION

In assessing the value of the anesthetic agent, we feel that evidence indicates it is still producing benefits on the second and third postoperative days. That this may be of sufficient duration in contradistinction to

AN EXPERIMENTAL STUDY OF THE COMPARATIVE EFFICACY OF HEPARIN AND DICUMAROL IN THE PREVENTION OF ARTERIAL AND VENOUS THROMBOSIS

WILLIAM B KIESEWETTER M D and HARRIS B SHUMACKER, Jr., M.D.,
New Haven, Connecticut

THE value of the anticoagulant drugs heparin and dicumarol has been well established in recent years. The two drugs differ considerably in cost, methods of administration, and means of control of safe and effective dosage. They also differ somewhat in regard to the reactions and complications which may occur in hypersensitive individuals or with overdosage. It is of paramount importance that proper selection of the anticoagulant agent of choice must take into consideration, in addition to these factors, the comparative efficacy of the two drugs in the prevention of arterial and venous thrombosis. As far as we can ascertain, no such study has been recorded in the literature. The experiments reported in this communication were undertaken in an effort to compare, under controlled experimental conditions, the reliability of the two drugs in the prevention of arterial and venous thrombosis.

MATERIALS AND METHODS

The experiments were carried out upon healthy mongrel dogs ranging in weight from 5 to 20 kilograms; the majority weighed from 10 to 15 kilograms. The common carotid arteries, the external jugular veins, and the femoral arteries and veins were utilized. These vessels proved particularly suitable for the purpose of the study, being easily accessible, sufficiently large, and with few enough branches that a fairly long segment could be isolated with ease. The axillary vessels were not found suitable because of their small size, numerous branches, and relative inaccessibility. The

radial veins in the forepaw did not prove satisfactory either when exposed directly by operation or when injected through the intact skin. In most of the experiments only one of the jugular veins was traumatized, the other being used for withdrawal of blood for study.

In our preliminary efforts to find an efficient and reproducible means of inducing thrombosis in a high percentage of untreated animals, and yet one capable of prevention by the use of anticoagulants, numerous methods were tried and subsequently abandoned. They included the following attempts to produce venous thrombosis: (1) Double partial ligation with silk or No. 000 chromic catgut with a 1 inch segment between the ligatures, as outlined by Potts and Smith; (2) double partial ligation with silk or catgut combined with forceful stretching of the intervening segment as suggested by Rabinowitch and Pines; (3) partial penetrating ligatures of silk or No. 000 chromic catgut so as to narrow the lumen and at the same time leave a foreign body inside the intimal layer of the veins. Preliminary attempts to obtain satisfactory arterial thrombosis included the methods just mentioned and also the following: (1) application of one Kelly clamp at full tension across the artery for 20 seconds; (2) application of several Kelly clamps at full tension across the artery for 20 seconds; (3) double partial ligation with silk or catgut and application of multiple Kelly clamps at full tension across the intervening segment for a period of 20 seconds. These methods were all discarded because the results obtained with each were too variable.

The methods finally adopted and applied in all the animals included in this study were as follows. The arteries were dissected free and

From the Department of Surgery, the Yale University School of Medicine, New Haven, Connecticut. Aided by a grant from the Office of Naval Research, The United States Navy.

blood was excluded from a segment 1 to 2 inches in length by the use of rubber band tourniquets. The artery was transected through half its circumference with small ophthalmic scissors. The adventitia was not stripped only long coarse fragments hanging from the artery were clipped off. A rough closure with little or no eversion of the approximated margins was effected by a continuous over and over suture of No 5 Deknatel silk. The carotid arteries were cut and closed transversely while the femoral arteries were cut transversely but closed longitudinally. There was, consequently definite narrowing of the sutured femoral arteries. Hemostasis proved a considerable problem in those animals treated with heparin or dicumarol. The bleeding could be brought under control in almost all instances however by use of gentle pressure over the suture line, additional sutures and liberal use of hemostatic globulin. The veins were similarly dissected free and blood was excluded from a one to two inch segment by rubber band tourniquets. The isolated segment, free of blood was then distended maximally with 5 per cent sodium morrhuate solution which was introduced through a fine needle. It was left in the vein for a measured period of from 3 to 4 minutes. The morrhuate was then withdrawn by aspiration the rubber bands were released, and blood flow re-established. Nembutal anesthesia was used. All the operations were carried out under aseptic conditions. An effort was made to achieve complete hemostasis before closure. Silk ligatures were used, and the skin was approximated with interrupted black silk sutures. The dogs were all fed the usual kennel ration both before and after operation.

Except where it is specifically mentioned, the vessels were not reexamined until 7 days after operative trauma. First the exposed vessel was inspected grossly and palpated gently for thrombosis at and near the site of the previous trauma. Notes were made concerning the presence or absence of free flow of blood through this area, normal filling of the veins proximally and distally and pulsation of the arteries distal to the sutured area. Such observations were usually sufficient to establish whether thrombosis had, or had not, oc-

curred. In doubtful cases the veins were transected proximal to and the arteries distal to the injured segment in order to see whether blood flowed freely through it. Finally the vessels were excised and opened widely in order to verify the other observations.

Before and each day following operation, blood was withdrawn by venipuncture for determination of coagulation time, fibrinogen level and prothrombin time. The Lee White two tube method was used for determination of coagulation time in some of the later experiments this method was supplemented or replaced by the capillary tube technique of Kruse and Mores. Fibrinogen estimation was carried out according to the technique of Mylon, Winternitz and de Suto-Nagy. Prothrombin times were determined both on whole and diluted plasma. Quick's method (7) was used for whole plasma while the Wright Prandoni modification was employed on a 25 per cent dilute plasma, fresh 0.5 per cent fibrinogen in normal saline solution being used as the diluent. In order to be able to express the prothrombin values in per cent of normal curves were established by multiple determinations upon various dilutions of samples of normal dog plasma in a manner similar to that utilized by Quick in establishing normal curves for human and animal plasma (6). Whole plasma was diluted to a concentration of 75, 50 and 25 per cent and the prothrombin time was determined for each sample. Using a minimum of 10 different plasma readings for each dilution, we obtained a mean from which a straight line graph on log-log paper was constructed. This same technique was utilized to obtain a straight line representation for samples of normal undiluted plasma with prothrombin times of 4, 4.5, 5, 5.5 and 6 seconds these values constituted the range of prothrombin times encountered with the type of thromboplastin used. In order to obtain straight line representation for the dilute plasma, we repeated the above process using a primary 1:4 dilution as 100 per cent and in turn diluting this to 75, 50 and 25 per cent. Again samples with whole prothrombin time values varying from 4 to 6 seconds were used. While we do not feel that our percentages were strictly accurate we do believe they did not have

much over a plus or minus 3 per cent error which was sufficiently accurate for this study.

The administration of anticoagulants was always begun beforehand in order to have an effective level at the time the vessels were traumatized. Dicumarol was administered intravenously in a sodium hydroxide solution made according to instructions of Overman and his associates, a 10 milligram per cubic centimeter solution was used. The drug was given 24 hours before operation. In the initial experiments a 25 milligram dose was given preoperatively and as frequently after operation as was required to maintain the prothrombin percentage at the desired level. In all succeeding experiments the dicumarol was given initially in doses of 2 or 3 milligrams per kilogram of body weight and subsequently in doses of 1 or 2 milligrams per kilogram given when indicated by the daily prothrombin determinations. Crystalline heparin was administered intravenously immediately before operation. The dosage ranged from 0.5 to 4 milligrams per kilogram of body weight; the drug was given at intervals of from 2 to 4 hours. When heparin in Pitkin's menstruum (3) was used it was given intramuscularly or subcutaneously in doses ranging from 5 to 10 milligrams per kilogram of body weight. In some animals heparin was given intermittently by intravenous injection throughout the day while a single injection of heparin in Pitkin's menstruum was administered in the evening in order to maintain a prolonged coagulation time until the following morning. At least one coagulation time estimation was performed daily upon each dog, the blood generally being withdrawn immediately before an injection of heparin in order to determine the lowest coagulation times prevailing. In some of the dogs the coagulation time was tested just before a number of successive injections of heparin. In addition some coagulation time studies were performed shortly after injections of heparin in order to study maximal effects.

RESULTS

Experiments were carried out upon 84 dogs but only 70 of these were suitable for statistical comparison and are included in this analysis. The remainder is comprised of the

animals used in the preliminary survey of methods of producing thrombosis; a few died of causes necessitating their elimination from this study. The last group is included however in the analysis of complications resulting from the use of the two anticoagulant agents. Fifteen dogs served as controls, 25 received dicumarol in varying amounts and 30 were heparinized for different periods of time.

Altogether 228 veins and 177 arteries were traumatized and subsequently examined for thrombosis. Since all of the veins were roughly of the same caliber they are grouped together. The carotid arteries had an external diameter of from 4 to 5 millimeters and are grouped together for purpose of analysis, as large arteries. The femoral arteries were smaller, having a diameter in the neighborhood of 3 millimeters; they are referred to as small arteries. In addition, as we have mentioned previously, the diameters of the femoral arteries were deliberately reduced further by suturing the transverse incision longitudinally.

Certain data relating to prothrombin time and coagulation time values are included in the tables. It should be pointed out that our observations established the fact that the administration of dicumarol 24 hours before operation resulted in a diminishing level of prothrombin at the time of operation and an increasing effectiveness of the drug during the critical early postoperative period. Attention should also be called to the fact that our studies revealed that heparin in Pitkin's menstruum given in the dosage employed invariably resulted in adequate prolongation of coagulation time for a period ranging from 12 to 24 hours, thus insuring increased coagulation time during the night period in which intermittent intravenous heparin was omitted in certain instances. Repeated clotting time studies showed that rarely if ever was the clotting time kept elevated during the entire 4 hour period between injections of heparin, regardless of the dosage employed.

Fifteen dogs served as controls. The vessels of 9 of them were examined 7 days after operation (Table 1, section 1). This period of time was chosen arbitrarily as one in which we might be reasonably sure that thrombosis would be evident were it destined to occur. In

this group comprising 27 veins, 14 small and 18 large arteries, thrombosis was present in 85 2 per cent of the veins, 91 9 per cent of the small arteries, and 66 7 per cent of the large arteries. In order to learn whether thrombosis would be evident much sooner if it were going to occur at all the vessels of 3 dogs were examined 24 hours and 3 others 48 hours after injury. The incidence of thrombosis in the first (24 hour) group was 100 per cent for veins, 50 per cent for small arteries, and 83 3 per cent for large arteries. In the latter (48 hour) group the figures were 100 per cent 83 3 per cent, and 66 7 per cent, respectively. The two groups combined had an incidence of thrombosis of 100 per cent for veins, 70 per cent for small arteries and 75 per cent for large arteries. These results do not differ ma-

tenally from those found in the group examined 7 days after operation. In order to ascertain whether any additional thrombosis occurred after the early examination the vessels of one dog (No 321) were examined with aseptic precautions in 24 hours and later 7 days after operation. Another (No 328) in 48 hours and again 7 days after operation. In neither were there more arterial or venous thromboses in 7 days than were present in 24 or 48 hours. Altogether it appeared evident that thrombosis following the experimental vessel trauma utilized in these studies occurred within the first 48 hours. Combining all the control studies it was found that there were thromboses in 91 1 per cent of the veins, 83 3 per cent of the small arteries, and 70 per cent of the large arteries.

In Table II are listed blood studies upon the control animals examined 7 days after the vascular injury. The coagulation time was generally shortened on the first postoperative day. In 5 of the 9 dogs there was a measurable increase in circulating prothrombin but in only 4 of the 5 was the prothrombin per cent increased with significant regularity. The fibrinogen determinations revealed wide variations from one day to another but seemed to follow a fairly regular pattern consisting of a sharp rise on the first or second day with gradual subsidence toward normal. There appeared to be a tendency in a few animals for a secondary rise to occur on the sixth or seventh day.

HEPARIN

The effect of varying amounts of heparin upon the incidence of thrombosis was studied in 30 dogs. Eleven animals were given crystalline heparin intravenously before operation and every 4 hours after operation for a varying number of days (Table III section 1). Two were treated for 7 days, 6 for 6 days and one each for 5, 4, and 3 days. The average duration of treatment was a little less than 6 full days. In a few dogs heparin in Pitkin's menstruum was given every evening in sufficient amount to maintain a good anticoagulant effect until the following day. The details of the drug administered are given in Table IV. Under this regimen the incidence of thrombosis at the end of the period of treatment was 56.3 per cent in the case of veins, 6.7 per cent in the case of small arteries and 9.5 per cent in the case of large arteries.

The results of the blood studies in these animals are recorded in Table IV. Of considerable interest is the wide fluctuation in coagulation time from one examination to another in the same animal and in different animals being given the same dosage of the drug. Of particular significance is the fact that a prolonged clotting time was generally not maintained in any animal for the entire duration of the experiment. Indeed the clotting time in all animals tended to return to a normal or near normal level periodically before each new dose of heparin was administered. For the sake of brevity all of the coagulation times performed are not listed only the first test per

formed each day is given. The inconstancy of the prolongation of clotting time is not so evident from the data recorded in the table, as it is from repeated clotting time studies done just before several successive injections of heparin. Only in one dog (No. 319) was any tendency to hyperprothrombinemia manifested after operation while in 2 (Nos. 277 and 311) the prothrombin percentage was reduced on a single occasion when the coagulation time was very prolonged. On numerous occasions a markedly prolonged coagulation time was found without simultaneous reduction in prothrombin. The pattern of the fibrinogen studies after operation was similar to that noted in the controls.

Because of the failure to maintain a prolonged coagulation time constantly in these experiments and because of the rather poor effectiveness of this therapy in the prevention of venous as compared with arterial thrombosis, more adequate heparinization was carried out for a short period of time in dogs with traumatized veins. Six dogs operated upon in the usual manner, were given large doses of heparin in Pitkin's menstruum. Careful checks of coagulation time revealed a constant and effective prolongation in each instance during a period of 24 hours. At the end of this period the veins of each dog were examined under aseptic technique; the wounds were resutured and the vessels of the 3 which survived for 1 week were re-examined at the end of that period. Precisely the same type of experiment was carried out upon 6 additional dogs with the exception that effective heparinization was maintained during the first 48 hours at the end of which time the first inspection of the vessels was made. In the first group only 9.1 per cent of the veins were thrombosed at the end of 24 hours while 45.5 per cent were thrombosed in 7 days (Table III section 2). Similarly in the second group 20.8 per cent of the veins were thrombosed in 48 hours and 66.7 per cent in 7 days. In 2 additional animals the clotting time was maintained constantly prolonged for 72 hours. At the end of this period none of the veins was thrombosed, but in 7 days thrombosis was present in 57.1 per cent. If the results of these 3 experiments are combined, it is seen that at the end of

adequate heparinization for 1, 2, or 3 days only 7 of 54 veins were thrombosed (12.9 per cent) while in every animal which survived for a week after operation additional thromboses had occurred after cessation of treatment. Seventeen of the 30 traumatized vessels in the surviving animals were thrombosed in 7 days (56.7 per cent).

Five dogs were given a single intravenous dose of heparin in amounts of 2 milligrams per kilogram of body weight just before operation. No further anticoagulant therapy was administered. At the end of 1 week thrombosis was present in 62.5 per cent of the veins, 10 per cent of the small arteries and 30 per cent of the large arteries (Table III section 3).

DICUMAROL

The effect of dicumarol upon the incidence of thrombosis was studied in 25 dogs which received the drug in varying dosage and for different periods of time. In 10 animals treated before, and for an average of 6 days after, operation and in which the prothrombin per cent was kept rather consistently low thrombosis occurred in 41.4 per cent of the traumatized veins, 50 per cent of the small arteries and 15.8 per cent of the large arteries (Table V, section 1). Five of them were treated for 7 days, 3 for 6 days, 1 for 5 and 1 for 3 days. The details of administration of the drug and of the blood studies are recorded in Table VI. The prothrombin levels were almost uniformly low and the results are not significantly different in those in which all the values were very low and in those in which the prothrombin percentage was somewhat higher on one or more determinations. The blood fibrinogen response to the operative procedure was essentially the same as that noted in the control group. The coagulation time studies revealed a direct relationship to the prothrombin level, an increase in coagulation time was generally noted when the prothrombin percentage was below 20.

In 4 dogs a low prothrombin level was not constantly maintained. In one the prothrombin percentage was 100 on the third day in the others it was 50 or greater on several occasions. In these animals the incidence of thrombosis was greater than in the first group,

P—Preoperative.

O—Day of operation. The blood studies were performed before the operation.

Dog 215 died. Large hematoma of thigh.

Dog 215 died. Massive hemorrhage from femoral artery.

the values being 75 per cent for veins 75 per cent for small arteries and 41.9 per cent for large arteries (Table V section 2)

In 6 dogs in which only veins were traumatized, excessive amounts of dicumarol were given for the first 24 or 48 hours with maintenance of very low prothrombin levels. In order to terminate the anticoagulant effect each animal received a transfusion of 150 cubic centimeters of fresh blood and 30 milligrams of vitamin K parenterally. In 3 the anticoagulant therapy was maintained for 24 hours in 3 for 48 hours. In the first group none of the veins were thrombosed at the end of 24 hours, while 36.4 per cent were thrombosed at the end of a week. In the latter group one-third were thrombosed in 48 hours and 60

per cent in 7 days. When the two are combined it is seen that the incidence of venous thrombosis was 16.7 per cent at the end of the short period of treatment and 47.6 per cent at the end of the week (Table V section 3)

Five dogs were given 5 milligrams per kilogram of body weight of dicumarol 24 hours before operation and no further anticoagulant therapy. One week after operation 75 per cent of the traumatized veins, none of the small arteries, and 44.4 per cent of the large arteries were thrombosed (Table V, section 4)

COMPARISON OF RESULTS IN ANIMALS TREATED WITH HEPARIN AND WITH DICUMAROL

Table VII compares the incidence of thrombosis from 5 to 7 days after operation in un

TABLE VII.—RESULTS OF HEPARIN THERAPY FOR FROM 5 TO 7 DAYS AND OF DICUMAROL THERAPY ADEQUATE TO MAINTAIN A RATHER LOW PROTHROMBIN LEVEL FOR FROM 5 TO 7 DAYS

Method of treatment	Veins		Small Arteries				Large Arteries			
	Number transacted	Number thrombosed	Number transacted	Number thrombosed	Number transacted	Number thrombosed	Number transacted	Number thrombosed	Number transacted	Number thrombosed
Name	27	3	25		13	9	8		66	7
Heparin	26	5	6	1		9	7			8
Dicumarol	26		15		13	8	50	7	2	7.6

treated animals, animals treated with heparin for the same period, and animals treated for the same length of time with dicumarol in amounts sufficient to maintain the prothrombin level fairly constantly at about 30 per cent or less. Eighty five per cent of the veins were thrombosed in untreated dogs, 61.5 per cent in those treated by heparin and 46.2 per cent in those treated with dicumarol. The figures for small arteries are 92.9 per cent, 9.1 per cent, and 50 per cent, respectively and for large arteries 66.7 per cent, 11.8 per cent, and 17.6 per cent. There is no statistically significant difference in the incidence of thrombosis of veins and large arteries in the groups treated by heparin and dicumarol the incidence in small arteries is certainly significantly higher in those treated by dicumarol.

In Table VIII the incidence of venous thrombosis in untreated animals and in animals intensively treated with heparin and dicumarol for 24 or 48 hour periods is compared, the vessels being examined 24 or 48 hours after operation in all 3 groups. It will be seen

TABLE VIII.—COMPARISON OF INCIDENCE OF VENOUS THROMBOSIS 24 AND 48 HOURS AFTER OPERATION IN UNTREATED DOGS AND IN DOGS TREATED INTENSIVELY WITH HEPARIN OR DICUMAROL

Treatment	No. of veins transacted	No. of veins thrombosed	Percentage thrombosed
None	18	8	100
Heparin	45	7	5
Dicumarol	24	4	16

TABLE IX.—COMPARISON OF INCIDENCE OF THROMBOSIS 7 DAYS AFTER OPERATION IN UNTREATED DOGS AND IN DOGS TREATED WITH A SINGLE DOSE OF HEPARIN OR DICUMAROL

Treatment	Veins		Small Arteries				Large Arteries			
	Transacted No.	Thrombosed	Transacted No.	Thrombosed	Transacted No.	Thrombosed	Transacted No.	Thrombosed	Transacted No.	Thrombosed
Name	27	3	25		13	9	8		66	7
Heparin	6	10	8	1	20				10	3
Dicumarol	16		75						9	44.4

that while all of the veins in the control group were thrombosed only 15.2 per cent of those in animals treated with heparin and 16.7 per cent of those in animals treated with dicumarol were thrombosed. Obviously both drugs were effective but not statistically different from each other in value.

In Table IX the incidence of thrombosis 7 days after operation is compared in untreated animals, those treated with a single dose of heparin and those treated with a single dose of dicumarol. It is apparent that the anticoagulants given in this manner and this is particularly true of dicumarol had little demonstrable efficacy in lowering the incidence of venous thrombosis. In the control group 92.9 per cent of the small arteries were thrombosed in the heparinized group 10 per cent, and in those given dicumarol zero. It is apparent that a single dose of either anticoagulant lowered the incidence of thrombosis remarkably the results are not significantly different in the 2 treated groups. Sixty seven per cent of the large arteries were thrombosed in the control group 30 per cent in those given heparin and 44.4 per cent of those given dicumarol. Here, too, the anticoagulants appear to have resulted in a significant lowering of the incidence of thrombosis without a statistically significant difference in the effectiveness of the 2 agents.

COMPLICATIONS

Of 35 animals treated with heparin 25 or 71.4 per cent had evidence of subcutaneous hemorrhage. Of these 25 19 (76 per cent) had

all hematomas. Three or 12 per cent profusely at the time of operation that more of the vessels being sutured re- gation. Nine or 36 per cent of those there was bleeding died of postopera- tive hemorrhage.

dogs treated with dicumarol 11 or 44 bled subcutaneously. Of these 11 5 (45 per cent) had large 3 (27 3 per cent) small 2 (18 2 per cent) and 3 (27 3 per cent) small hema- tomas. None required ligation of the artery and none bled. Three or 27 3 per cent of the dogs which bled postoperatively died as the result of hemorrhage.

Within 3 menstruum heparin was given on more occasions to 28 dogs 16 or 57 1 per cent had some serious complication. Five (31 2 per cent) developed a slough at one or more of the sites of injection. Nine (32 1 per cent) had marked edema and inflammation in the thigh. Two (7 1 per cent) died of angrene.

DISCUSSION

analyzing the results of this study it is important to call attention to several facts. In the first place, in all the long term experiments heparin was given in amounts and at intervals which were generally inadequate to maintain a prolonged prolongation of coagulation time. In the second place, the clotting time tended to return to or near normal level before each subsequent injection of heparin. In this respect the technique employed was equivalent to the technique commonly employed in patients in which the heparin was given intermittently. For example, the intravenous administration of 50 milli- grams of heparin at 4 hourly intervals in man was usually attended by a highly fluctuating clotting time curve, the values rising sharply after each dosage and falling to a normal level before each new injection. In similar animal experiments in which dicumarol was used instead of heparin, the prothrombin values were kept at very low levels which are ordinarily considered dangerous in patients. In our analysis of the few exceptional experiments in which the prothrombin values were not kept at such a low level are segregated

and are not included in comparing the two anticoagulant agents. Thus in interpreting the results we must keep in mind the fact that the heparin effect was comparable to that generally considered safe in man, while the dicumarol effect was generally of a degree thought to be dangerous in man.

In the second place it should be emphasized that the experimental conditions of arterial and venous damage were of extreme degree. The arterial incisions were repaired in a fashion eliminating those details of technique known to foster a successful outcome. The veins were severely injured. Such extremes of trauma were necessarily adopted in order to achieve thrombosis consistently in most of the untreated animals. It must be borne in mind however that the effect of therapy was evaluated under more severe conditions of local vascular injury than are apt to be encountered in patients.

In the third place it would seem evident that any clinical application of the results of this study can be made properly without too much concern over the numerous hemorrhagic complications which were encountered. The persistent bleeding and the large hematomas which occurred all too commonly were generally due to hemorrhage from the line of suture of the repaired arteries. In experiments in which only the veins were traumatized significant hemorrhagic complications were very few. Since the arteries were deliberately sutured with purposeful disregard of principles which not only provide the best chance of successful healing but also give maximal insurance against leakage there is little wonder that control of bleeding was difficult in the presence of full anticoagulant effect. The recent experience of Shumacker, Ahramson and Lampert suggests that reparative surgery of peripheral arteries can be carried out safely in the presence of a full anticoagulant effect of dicumarol or heparin or of the two drugs in combination. Though hematomas were more common under such conditions than when anticoagulants were not used, careful observation of the patient and proper treatment precluded serious difficulties. It has become apparent on the other hand, that the immediate use of anticoagulants is

unwise when surgery is performed in the thoracic or peritoneal cavities or in other situations where bleeding may go unrecognized until the patient's life and the success of the operative procedure are jeopardized. The large recorded cumulative experience with heparin and with dicumarol in the treatment and prevention of venous thrombosis and embolic sequelae in man testifies to the relative safety of the drugs in these conditions provided the recognized means of control are carefully followed.

In comparing the efficacy of heparin and dicumarol in the prevention of venous thrombosis no significant difference was noted. This was true in experiments involving both a short or a more prolonged period of treatment. It seems unlikely that the comparatively equal effectiveness of the 2 drugs in the experiments involving a prolonged period of treatment is vitiated by the more intense and consistently maintained anticoagulant effect secured with dicumarol and the more intermittent, inconsistent prolongation of clotting time with heparin. In the experiments in which treatment was of one or two days' duration and in which a marked consistent anticoagulant effect was maintained in the heparinized dogs as well as in those treated with dicumarol no significant difference in the results was noted.

It is exceedingly difficult to be certain that any two groups of patients are adequately controlled in regard to important details such as local venous trauma, stasis, innate tendency to intravascular clotting etc. Nevertheless such large numbers have been treated with heparin and with dicumarol with comparably excellent results as to suggest that there is little to choose between them with regard to efficacy. To be sure, in the reported cases of patients treated with dicumarol the prothrombin time has generally been kept constantly at a fairly low level while in those treated with heparin the drug has been administered in a fashion recognized as inadequate for constant prolongation of clotting time. Whether contrary to our experimental studies, the results would be superior in patients treated with heparin in such a manner as to maintain consistently a prolonged clotting time, only further experience will reveal. Un-

less new experimental or clinical experiences throw a different light upon the subject, it would seem wise from the standpoint of economy and rapidity of action to begin treatment with adequate amounts of both heparin and dicumarol and to discontinue the heparin once a good prothrombin reduction has been achieved with dicumarol.

Our experiments demonstrated that thrombosis following sodium morrhuate trauma to veins occurs early there being as high a percentage of thrombosis in vessels inspected in 1 or 2 days as in those examined in 7 days. It is significant, however, that the prevention of thrombosis for the first day or so with adequate anticoagulant therapy does not preclude subsequent thrombosis once the treatment has been discontinued. It would appear that once the vein has been injured the best results can be obtained only if treatment is continued until healing of the vessel is complete.

In contrast to the results with venous injury our experiments showed the anticoagulants to be considerably more efficacious in preventing arterial injury and demonstrated an apparent inequality in the effectiveness of the two agents. If those animals treated with dicumarol in which the prothrombin level was not kept rather constantly low are omitted from consideration, there was no significant difference in the incidence of thrombosis in the larger arteries in dogs treated with the two drugs (15.8 per cent with dicumarol 9.5 per cent with heparin) but there was a much higher incidence of thrombosis of small arteries in those treated with dicumarol (50 per cent, as compared with 6.7 per cent). It must be recalled again that the prothrombin percentage was generally kept consistently very low in the animals treated with dicumarol and that the clotting time often rose to normal levels in those treated with heparin. No significant difference in thrombosis of arteries was noted a week after injury in dogs treated with a single dose of heparin or a single dose of dicumarol. In these experiments however the heparin effect lasted only a few hours while the dicumarol effect lasted for a day or more. Taking into consideration all of the experiments proper interpretation from the standpoint of clinical applicability is rather

difficult. Since arterial repair in man is ordinarily performed upon vessels as large or larger than the carotid arteries of dogs and since no difference was noted in the incidence of thrombosis of those vessels in dogs treated by heparin or by doses of dicumarol which were generally effective in keeping the prothrombin time very low one might reason that the two drugs should be equally effective in preventing arterial thrombosis in patients. Since our results were obtained however with heparin in doses comparable to those which are safe clinically and with doses of dicumarol resulting in prothrombin levels in the dangerous zone, one might on the other hand reason that if the two drugs are given in safe dosage better results might be anticipated with heparin. It is our opinion that this interpretation is probably correct. Furthermore maximal utility of an agent is often best evaluated under extreme conditions. There can be no doubt that heparin was more effective than dicumarol in preventing thrombosis of the small femoral arteries even though the former drug was generally given in doses inadequate to maintain constant prolongation of clotting time while the latter was given in amounts usually sufficient to keep the prothrombin percentage very low. Until further data are available it would seem wise to use heparin at least for the first 5 or 6 days in cases of arterial injury or repair. It would also appear wise to use dicumarol in conjunction with the heparin and to continue its administration until it is felt that all hazard of thrombosis is past. Our experiments do not provide an answer to the question as to how long the danger of thrombosis exists after arterial injury or repair. It has been the policy of one of us (HBSjr) arbitrarily to continue anticoagulants for 2 or 3 weeks after arterial repair.

Several other observations noted in the course of this study deserve brief discussion. In the latter part of the experiment we used the Kruse method for coagulation time and found it much more satisfactory than other methods. The blood can be obtained by pricking the skin; the temperature factor is controlled; the method requires less agitation of the tubes than does the Lee-White method; the end point is precise; the normal values are

shorter than those obtained with the Lee-White method and even when greatly prolonged are not so long as to exhaust the observer. Finally, it was found that the results could be checked with a smaller margin of error. It is felt that the method is deserving of more widespread trial.

The intravenous method of administration of dicumarol in basic solution was found most satisfactory. It has the advantage of precision of dosage and elimination of the variables of intestinal absorption. By its use the maximal effect is achieved more quickly than with oral administration. In hundreds of injections no instances of thrombosis of the injected veins were noted. It would appear profitable to pursue further the possibility of placing dicumarol in some solution suitable for clinical intravenous administration.

The Pitkin's menstruum used was similar to that employed by Loewe and his co-workers in their original work. It was found painful and was frequently followed by sloughing of the skin, massive edema and inflammatory reaction and occasionally by gas gangrene. It has the advantage of more prolonged action and cheaper cost than intravenously administered heparin. If the newer modifications prove to be devoid of distressing local reactions or should other efforts result in new means of administering heparin in some form which will produce a prolonged effect without local or general reaction, heparin therapy will be rendered easier, cheaper and more effective. Our experiments convinced us that if a constantly prolonged clotting time is desirable it can better be achieved by more frequent intravenous injection of small amounts of heparin rather than by giving larger doses at greater intervals. It has been inferred from certain clinical observations that heparin may be effective when given in doses and at intervals inadequate to maintain a constantly prolonged coagulation time. Our experiments tend to substantiate such inferences though they suggest that heparin is less effective in such dosage than in amounts which result in constant prolongation of clotting time. This problem is important and requires further intensive study. It will certainly be wise to study effects of heparin other than prolongation of clotting

time such as its effect upon platelet adhesiveness. Perhaps other manifestations of heparinization are evident after the clotting time has returned to normal

SUMMARY AND CONCLUSIONS

1 Experiments comparing the effectiveness of heparin and of dicumarol in the prevention of arterial and venous thrombosis following injury are reported.

2 Methods of producing experimental venous and arterial thrombosis are described.

3 Thrombosis following injury to the vessels appeared to occur early certainly during the first day or two

4 Under the conditions of the experiment, dicumarol and heparin appeared equally effective in reducing the incidence of venous thrombosis.

5 Under the conditions of the experiment, anticoagulant therapy was more efficacious in preventing arterial than venous thrombosis. Using doses of dicumarol adequate ordinarily to maintain a very low prothrombin level and

of heparin generally inadequate to maintain a constantly prolonged coagulation time, statistically superior results were obtained with heparin in preventing thrombosis of injured small arteries the results were not statistically different in preventing thrombosis in larger arteries.

CARCINOMA OF THE PANCREAS

A Clinicopathologic Survey

GERSHON B. SILVER, M.D., and RUTH K. LUBLINER, M.D. New York, New York

IN an attempt to survey and correlate clinical and postmortem findings in cases of neoplastic disease at Montefiore Hospital, it soon became evident that great confusion in diagnosis and profound differences between clinical impressions and postmortem findings were present in cases of cancer of the pancreas. We found that unless the patient exhibited jaundice the correct diagnosis was most often missed and unsuspected. Therefore it was decided to review all instances of cancer of the pancreas in which postmortem examinations were made from the years 1919 to 1946. One hundred and four cases were studied, which represented 3.8 per cent of all necropsies of neoplastic disease during this period. This incidence is higher than the figures of 1 and 2 per cent which are usually mentioned.

With improved methods in surgery of the pancreas, it is becoming more important today to recognize the syndrome of pancreatic malignancy early at a stage when radical operative treatment can be effected. Unfortunately except for cancer involving the head where jaundice may be present, the evidence on which such a diagnosis is based is often indirect. It is therefore, in cases of involvement of the body where the majority of errors in diagnosis are made. The poll of impressions by Berk is adequate testimony to this fact. In this poll which involved questioning of fourth year medical students, internes, residents, graduate students and general practitioners it was seen that 43 per cent of these younger and presumably better trained persons expressed the belief that painless jaundice was the most common and characteristic sign of cancer of the pancreas whereas 50 per cent stated that simple jaundice was the predominant feature many qualifying this by stating

that it was progressive. Only 2.5 per cent expressed the belief that pain was an outstanding symptom. A relatively insignificant number mentioned other important signs and symptoms such as weight loss, anorexia, gastrointestinal disturbances, enlarged gall bladder, deformed duodenum or diabetes.

For clinical considerations we think it best and most practical to divide cancer of the pancreas into two types: (1) cancer of the head and neck and (2) cancer of the body and tail. Chauffard in 1908 differentiated the two clinically by the terms '*pancreatico biliare*' for cancer involving the head and '*pancreatico solaire*' for that involving the body, the former based upon the jaundice, the latter upon the relation of the symptom of pain to the solar or celiac plexus. The clinical description of cancer of the head dates back to Bard and Pic who in 1888 described 7 cases proved by autopsy. They pointed out that the symptoms and signs characteristic of that condition were progressive, persistent, painless jaundice, dilatation of the gall bladder, clay colored stools and cachexia.

The wisdom of such a differentiation has been questioned by some. Berk, for example, stresses the unreliability of this distinction if one uses operative findings as criteria. He mentions that even at autopsy overlapping involvement of various parts of the gland is common and that small areas of involvement by extension from the dominant area may affect the clinical picture. Levy and Lichtman could find only 19 among 122 cases—diagnosed by laparotomy or necropsy—in which the body and tail alone were affected and they mention that even in these 19 there was terminal involvement of the head. Incorrect conclusions as to the primary origin can be made even at operation in spite of the fact that the head is palpated and biopsy taken from it. (4) Similarly Ransom's (26) experience with 10

D. Islet cell		9
Body and tail		
Aberrant in liver	†	

*These cases are grouped with the carcinomas of the body and tail because the impression was that they arose primarily in the body.

†This case was published. See reference.

patients showed gross discrepancy between surgical and autopsy findings. The same holds true for differentiating at operation between cancer of the head of the pancreas and other cancers in that location which may produce jaundice such as cancer of the common bile duct or the ampulla of Vater. The diffuse involvement seen in some pancreatic cancers adds to the difficulties. However the above objections are concerned more with the difficulty of making the differentiation, especially in surgical material they do not argue against the validity of the principle. In our present material in which every case is verified by autopsy these objections do not hold. But even the differences in the autopsy findings have been questioned as being more apparent than real (18) the differences in tendency to extend and metastasize it is suggested may actually be due to a shorter course of the disease in cases of cancer of the head.

However predominance of the cancer in one part or the other of the pancreas is the rule rather than the exception. Not only do differences admittedly exist at autopsy but we feel that the clinical differences which manifest themselves are best understood by relating them to the various topographical areas of the pancreas. Therefore, we submit a clinical and pathologic analysis of our material which appears to indicate that an essential difference exists between the two types. In reviewing the histories which date back to 1919

TABLE II—LOCATION OF PRIMARY CARCINOMA OF PANCREAS (EXPRESSED IN PERCENTAGE)

Author	No. of cases	Head	Body and tail	Entire pancreas
Duff (9)	50	56	36	8
Kenney (20)	51	39	41	
Hick and Mortimer (17)	40	45	47	8
D'Amico Ogden and Halpert (7)	40	75	3	
Levens (21)	57	62	30	30
Graesser (16)	34	44	3	41
Our series	104*	57	33	11

*The two aberrant and islet cell tumors are not listed in the percentage column.

we must admit of some difficulties in gleanings statistical clinical data since they were taken by many different observers. In most cases involving the body and tail with the diagnosis unsuspected during life, certain pertinent x ray and laboratory studies were often missing.

The distribution of our 104 cases according to the primary location of the tumor is shown in Table I. In reviewing the autopsy series in the literature, a large variation is seen in respect to the relative percentage incidence of involvement of the head, as compared with that of the body and tail. This is indicated in Table II. In this table the series of Duff (9) of Kenney and of Hick and Mortimer agree most closely with our findings in that carcinoma of the body is nearly as frequent as that of the head. There is some confusion as to where the cases involving the entire pancreas should be placed. Heretofore most of these have been included with the carcinomas of the head. We feel that this is not justified, for in our series the autopsy findings as well as the clinical picture pointed to the body and tail as the primary site. In comparing autopsy with operative series, it should be noted that the latter always include a high incidence of cases with jaundice and thus have a tendency to exaggerate the percentage incidence of carcinoma of the head. For reasons just mentioned it is felt that the diagnosis of carcinoma of the body has been relegated to the back ground too often and that this condition occurs more frequently clinically than is appreciated. A more exact localization of the primary site of these tumors, both at opera-

TABLE III — SEX INCIDENCE IN CARCINOMA OF PANCREAS

	Male	Female	Total
Head and neck	39	18	57
Body and tail	16	17	43
Aberrant pancreas	1	1	2
Islets of Langerhans	1	1	2
Total No. of cases	67	37	104

tion and necropsy would lead us to a clearer understanding of the clinical picture.

Age and sex incidence In Table III the sex incidence is shown in the total number of cases in those involving head and neck and in those involving the body and tail. This table illustrates that there is a predominance of males affected, in a ratio of 1.8 to 1. This ratio of males to females however is somewhat greater in carcinoma of the head 2.2 to 1 and somewhat less in carcinoma of the body 1.5 to 1.

Chart 1 represents graphically the age incidence of this form of carcinoma. The peak of incidence of carcinoma of the head and neck occurs between 51 and 60 years whereas that for carcinoma of the body and tail occurs between 56 and 65 years.

Duration of illness Chart 2 represents an analysis of the life span in our cases. The graph indicates that the maximum incidence of death in cases involving the head and the neck of the pancreas was between the 4th and 6th month after symptoms appeared whereas that in cases involving body and tail was between the 10th and 12th month after onset. In some of the autopsy series showing comparative statistics wide variations are found. Grauer's cases show the widest variation including cases with survival ranging from 1 month to 7 years. In Duff's (9) series comprising 16 cases involving body and tail the average

TABLE IV — FREQUENCY OF PAIN, JAUNDICE AND WEIGHT LOSS IN CARCINOMA OF THE HEAD OF THE PANCREAS* (EXPRESSED IN PERCENTAGE)

Name	No. of cases	Pain	Jaundice	Weight loss
Franco (14)	40	85	78	60
Friedenwald and Morrison (15)	40	82	77	—
Zollinger and Kevorkian (30)	40	77	86	86
Rigney (28)	40	62	—	65
Our series	57	68	90	90

*These figures are based upon the incidence in the later stage.

Chart 1 Age incidence in carcinoma of pancreas. White areas, total number of cases; black areas, carcinoma of head and neck; crosshatched areas, carcinoma of body and tail.

duration of illness was 4.2 months, although one case of 19 months duration is not included. Among the 16 cases of carcinoma of the head which he reports the average duration is 4.6 months essentially the same as for those involving the body. More statistical information is necessary before conclusions can be drawn in regard to survival. The difference in duration which our cases seem to show may possibly be explained on the basis that carcinoma of the head interferes more with the vital functions of the pancreas, the liver and the biliary system by virtue of obstruction of the main duct systems.

CANCER OF THE HEAD AND NECK

From the standpoint of early diagnosis, the initial picture of the disease is of utmost importance. An attempt was made to analyze in our cases the earliest signs and symptoms. Chart 3 presents in the order of their incidence the signs and symptoms noted initially and later in our series of 57 cases expressed in percentages.

Table IV indicates comparative figures found in the literature for the main symptoms of pain, jaundice and weight loss. As may be

Chart 2 Survival time in carcinoma of head and body of pancreas compared. Black areas, head; crosshatched areas, body.

†A few cases at the extremes are omitted from the graph.

TABLE V—JAUNDICE IN THE EARLY AND LATE STAGES OF CANCER OF THE HEAD (57 CASES)

A. Early phase		No. cases
1. Jaundice alone as first sign		8
2. Jaundice concomitant with other signs and symptoms		3
Painless	8	
Painful	4	
3. No jaundice		43
4. Palpable gall bladder		4
B. Late phase		
1. Jaundice		3
Painless	6	
Painful	35	
2. No jaundice		6
3. Palpable gall bladder		1

seen from this table there is a relatively close degree of correlation.

Weight loss The incidence of 65 per cent weight loss initially as indicated in Chart 3 stresses its importance. The amount of actual loss in our cases was not always stated, but there were frequent references to the fact that it was marked and rapid. In those cases in which figures were available, it ranged from 6 to 60 pounds depending upon the time it was first noted. The average finding was a loss of 8.3 pounds per month.

In the autopsy protocols, emaciation was specifically mentioned in 23 out of these 57 cases.

Pain In 49 per cent, as Chart 3 indicates, pain was one of the first symptoms to appear. It was second only to weight loss in its frequency and much more common than jaundice. Vague distress and discomfort were not included as manifestations of pain. In the later stages of the disease, the incidence of pain rose to 68 per cent. Since, in that stage, the incidence of jaundice was 90 per cent, it is obvious that in a small number of cases the jaundice was painless.

Jaundice Chart 3 indicates that jaundice was a presenting sign in 25 per cent, and a late sign in 90 per cent. In 10 per cent, there was no clinical jaundice at any time. Table V indicates the relationship between the jaundice—the stage of the disease and other concomitant findings. In the 37 cases where jaundice appeared late there was a delay in its occurrence ranging from 1 to 43 months. Leaving out two extremes, one of 43 months, the

other of 30 in order not to weight the average, the delay was 3.8 months. Distended gall bladders were noted clinically in approximately one fourth of the jaundiced patients. Itching was present in 3 cases, in 1 before the onset of jaundice.

At autopsy jaundice was present in 34 cases as compared with the 57 cases in which it was noted clinically. This difference is explained by various operative procedures used to short circuit the biliary flow. However anatomic obstruction of the distal portion of the common bile duct was found at autopsy in 80 per cent of 57 cases, slightly less than the late clinical incidence of obstructive jaundice, 90 per cent. It has been noted by some (8) that obstructive jaundice may exist in the presence of a patent common bile duct, and this is suggested to be due to the lack of expulsive or contractile ability of the common duct by reason of invasion of its nerve supply or its wall by tumor. Obstruction of the distal portion of the common bile duct was associated with dilatation of the proximal bile passages in 38 of the 57 cases. In 28 of these, the gall bladder was also dilated. As noted previously in Table V only 12 of these 28 distended gall bladders were palpated clinically. There was intrahepatic bile stasis in 23 cases. In only 6 was this associated with biliary cirrhosis, in 7 with cholangitis. As a corollary of this, the pancreatic duct was dilated in approximately 50 per cent.

Shortcircuiting operations for relief of jaundice Since many of the jaundiced patients had shortcircuiting operations we compared the operated upon and nonoperated upon groups with respect to duration of life. Fifty cases were suitable for analysis. 30 patients had been operated upon. 20 had not been operated upon. The figures obtained were as follows: The onset of illness to onset of jaundice in nonoperated upon group was 3.8 months. In operated upon group 3.5 months. The onset of jaundice to death in nonoperated upon group was 3.5 months. In group operated upon 6.3 months. The total duration of illness in nonoperated upon group was 6.7 months. In group operated upon 9.8 months.

There was 0.6 month average delay between appearance of the jaundice and opera-

tion in the group operated upon. It appears from the figures that these short-circuiting operations prolonged life an average of 2.8 months.

Anorexia Anorexia was present as an initial complaint in 44 per cent. Although it is difficult to differentiate anorexia from various gastrointestinal disturbances, among which nausea and consequent loss of appetite would be prominent, it was mentioned specifically as such, in the histories concerned and we felt it was repeated often enough to bear distinction.

Weakness Weakness was noted in 35 per cent as an initial finding. It is an expected associate of anorexia and weight loss.

Gastrointestinal disturbances and obstruction In our 57 cases there were 15 or 26 per cent which showed various gastrointestinal disturbances in the initial stages. These included vomiting, diarrhea, constipation, epigastric distress, fullness, discomfort, cramps, belching, etc. As seen in Chart 3, 14 per cent of our cases, or more than half of those exhibiting initial gastrointestinal complaints, had some degree of high intestinal obstruction in the early stage of the disease. This finding was later verified by x-ray examination in 6 cases. Thus, in the earliest phase 11 per cent had positive x-ray evidence of high obstruction. In the later stages of the disease, a total of 79 per cent exhibited either obstruction or distortion in the pyloroduodenal area. Twenty-five cases, or 44 per cent, had the clinical picture of high intestinal obstruction, varying from partial to complete; of these 16 were proved by means of the x-ray and 3 at operation, while 6 were clinically diagnosed and later proved at post-mortem. On fluoroscopy and roentgenography of upper gastrointestinal tract 20 cases or 35 per cent had some distortion of pyloric end of stomach or the duodenal bulb although they had no obstructive symptoms or signs. Of these latter cases, 11 involved mainly the antrum of the stomach, and 9 the duodenum.

A deep epigastric mass was palpated in 33 per cent of the cases in the later stage. None was felt initially. Hematemesis or melena or both were present in 9 cases or 16 per cent. In 2 cases tarry stools were presenting symptoms.

At autopsy there were 11 cases with partial duodenal and 1 with pyloric obstruction in

Chart 3. Signs and symptoms of carcinoma of the head, initial and late—57 cases.

the total of 57 cases. There were 5 gastroenterostomies. In addition to these cases of frank obstruction, there were also 21 instances in which the tumor had invaded the wall of the duodenum and 3 the wall of the stomach without obstruction. As Chart 3 indicates, a higher incidence of obstruction was noted clinically but it should be remembered that only anatomical and not functional obstruction is seen at the autopsy table. With respect to intestinal bleeding, ulceration of the duodenum was present in 4 cases at post-mortem. In the remainder there was no obvious cause for the bleeding. However, portal obstruction whether by thrombosis, invasion or compression by tumor could produce intestinal bleeding as the result of congestion even in the absence of varices.

Hepatomegaly In 2 cases a large irregular liver was an initial sign; however, hepatomegaly was a much more prominent feature later in the disease and was present in 58 per cent, or 33 cases. Of these 15 were merely classified as large livers, 18 as irregular. The latter were clinically assumed to be metastatic.

At autopsy, metastatic lesions were found in the liver in 32 cases. In addition there was direct invasion of the liver in 1 case and extension to the porta hepatis in 4.

Metastases Chart 3 indicates that in 4 cases (7 per cent) metastases were responsible for the first signs and symptoms. These 4 cases were metastases to the skin in 1, large irregular livers in 2, and persistent diarrhea in the other. The latter finding was shown to be due to implantation of tumor on the ileum (post-mortem). In the final stages 11 or 19 per cent

TABLE VI.—INCIDENCE OF PAIN WEIGHT LOSS AND ANOREXIA IN CARCINOMA OF THE BODY OF THE PANCREAS* (EXPRESSED IN PERCENTAGE)

Name	No. of cases	Pain	Weight loss	Anorexia
Ransom (35)	16	100	94	9
Duff (9)	6	94	90	
Our series	43	98	98	28

*These figures are based upon the incidence in the later stage.

of the cases exhibited clinical evidence of metastases (excluding hepatomegaly). These were found in the late stages in the following sites: 3 in the pelvic peritoneum (Blumer's shelf), 2 in the lungs (x ray), 1 in the ribs, and another in the supraclavicular nodes.

At necropsy 10 of the 57 cases, or 18 per cent, exhibited no metastases.

Diabetes. Diabetes occurred in 2 of these cases. In both it was associated with chronic pancreatitis (autopsy). In 1 of the cases, it appeared with the presenting signs and symptoms.

Peripheral edema was seen in 2 cases.

Ascites was present clinically in 10 per cent and at autopsy in 28 per cent.

Steatorrhea and cretorrhea were present in 7 per cent in the later stages of the disease. The incidence of these findings is much smaller apparently than the incidence of pancreatic duct obstruction for at necropsy 50 per cent of the cases of carcinoma of the head exhibited dilatation of the pancreatic ducts. Fibrosis and atrophy of the body and tail were present in over half of these.

Errors in diagnosis. Diagnostic errors were made in 13 of these 57 cases. They were as follows: 6 were diagnosed as carcinoma of the stomach; 2 without jaundice were unsuspected of having cancer; 1 was diagnosed as coronary or gall-bladder disease; 1 as carcinoma of the ampulla of Vater; 1 as carcinoma of the gall bladder; 1 as biliary cirrhosis, and 1 as metastatic carcinoma of the liver; primary site unknown.

CANCER OF THE BODY AND TAIL

The 43 cases of cancer of the body and tail of the pancreas as classified in Table I were surveyed. The first presenting signs and symptoms are listed in Chart 4.

The frequency of some of the main complaints in this series is compared in Table VI with the series of Ransom (35) and Duff (9) and it is seen that there is fairly close agreement.

Pain. The figures in Chart 4 and Table VI emphasize the importance of pain in the clinical picture. It was uniformly severe and was present as an initial complaint in 70 per cent of our cases and later in 98 per cent.

Weight loss. Weight loss was about as prominent in the initial picture as pain. In our series of 43 cases 72 per cent gave this as a first complaint, and it was often noted as "rapid" and marked. It varied from 10 to 60 pounds, the average loss being 6.6 pounds per month. Emaciation was specifically noted in the autopsy protocols in 44 per cent.

Weakness was noted in about 41 per cent initially and progressed throughout the illness.

Anorexia was noted as an early symptom in 29 per cent, and was persistent.

Gastrointestinal disturbances and obstruction. Excluding anorexia, gastrointestinal disturbances were noted in 14 cases, or 33 per cent initially. Seven had constipation alone; 6 had generalized abdominal cramps and distention; 3 had diarrhea and 7 had nausea and vomiting. In the later stages of the disease these non-specific complaints rose to an incidence of 67 per cent, second only to pain in frequency. As in carcinoma of the head, a part of the complaints just enumerated can be attributed to obstruction by compression or invasion or both of the pyloroduodenal region by the tumor. Chart 4 indicates that high intestinal obstruction was exhibited in 6 cases, or about 14 per cent, as a presenting symptom; later the incidence rose to 37 per cent. These findings are similar in magnitude to those found in cancer of the head. Low intestinal obstruction was present in 7 cases, or 16 per cent, and only in the late stages. This was due either to extension of the process to the large bowel or to serosal metastatic implants. This type of obstruction and spread was not seen in cancer of the head.

An epigastric mass was noted clinically in only one case at an early stage, and is thus not an important presenting sign. However, a mass presumably the primary tumor deep in

the epigastrium or in the left upper quadrant, was felt in the later stages in 35 per cent, an incidence comparable with the 33 per cent found in cancer of the head.

On x ray examination 5 patients in the initial and 15 in the later stage exhibited some degree of pyloric or duodenal or both pyloric and duodenal distortion or obstruction. Of the latter 15 cases 9 involved the stomach only, 3 the duodenum only, and 3 both. Thus in findings were present in 35 per cent of the cases similar to cancers of the head and neck.

Hematemesis or melena or both were seen in 4 cases or 9 per cent, as presenting symptoms 1 bad hematemesis all 4 bad tarry stools. Adding to these 4 the cases in which bleeding occurred later there was a total of 7. Of these 7 or 14 per cent 3 bad hematemesis in addition to melena.

At autopsy 2 cases of pyloric obstruction and 3 cases of intestinal obstruction were found, the former caused by invasion of the stomach wall the latter by metastases. Three other cases showed invasion of the stomach wall, 14 had metastases to the intestines and 22 had diffuse peritoneal carcinomatosis all these failed to produce frank obstruction. The high percentage of distortion compression and displacement of the stomach and duodenum found on x ray examination may be explained by the fact that carcinoma of the body and tail has a tendency to invade the surrounding soft tissues and to fuse with the perigastric and peripancreatic lymph nodes to form large tumor masses. This was found at postmortem in 13 of our 43 cases.

Hepatomegaly Enlarged livers were found in a total of 25 cases or 58 per cent, a figure comparable to that seen late in cancer of the head. Of these 25, 11 were recorded as smooth 14 as irregular and definitely metastatic.

Anatomic findings showed the liver to be involved in 30 cases either by metastases or by direct extension.

Splenomegaly This was present clinically in 5 cases or 12 per cent in 1 case there was direct extension of the neoplasm to the spleen in 2 cases there was associated ascites. There was no splenomegaly noted clinically in the cases of cancer of the head.

	INITIAL		LATE

Chart 4. Signs and symptoms of carcinoma of the body initial and late—43 cases.

At autopsy, 5 instances of splenomegaly were found associated with carcinoma of the body 2 with carcinoma of the head 12 per cent and 4 per cent, respectively. The main reasons for the splenomegaly were compression invasion or thrombosis of the splenic vein.

Diabetes The association of diabetes with involvement of the body and tail was remarkable. There was a total of 14 instances of diabetes in our series of these 4 existed prior to and 4 coincided with the onset of the presenting symptoms, whereas 6 cases developed during the course of the disease. This is in marked contrast to the low incidence found in cancer of the head where it was present in only 2 cases, both with chronic pancreatitis. A much higher incidence of disturbances in carbohydrate metabolism would be present if the cases with temporary glycosuria hyperglycemia or with abnormal glucose tolerance curves were included.

Metastases As seen from Chart 4 metastases were already present as initial signs and symptoms in 10 cases or 23 per cent as compared with 7 per cent for the head. In the later stages metastases (extrahepatic) were found clinically in 26 cases or 60 per cent, in contrast to the 12 per cent found in the comparative stage of cancer of the head. This is consistent with the pathological findings. In 11 of these 26 cases exhibiting metastases, there was no associated enlargement of the liver in the remainder hepatomegaly was present. Table VII enumerates the types of clinical metastases noted above in both the initial and later phases in terms of the site of involvement.

TABLE VII.—SITE OF METASTASES NOTED CLINICALLY IN INITIAL AND LATE PHASES OF CARCINOMA OF THE BODY AND TAIL (43 CASES)

Site	Early	Late	Total
Intestine (intestinal obstruction)	5	4	9
Skin	2	1	3
Liver	6	14	20
Pleura and lungs	1	4	5
Spleen			2
Rectal shelf	0		10
Vertebrae	0	6	6
Epididymis and testis	0	2	2
Ovaries and uterus			1
Breasts	0		1
Lymph nodes	0	2	2
Omentum			1

As expected the incidence of metastases at autopsy was much higher than that seen clinically. The metastatic lesions found at post mortem and the remarkable difference in the extent between those seen in carcinoma of the head and neck and those of the body and tail are best illustrated in Table VIII. It is pertinent to note that at autopsy only 2 cases or 5 per cent of these 43 showed no metastases whereas in cancer of the head 10 of the 57 or 18 per cent were free of spread. The difference in the invasive qualities of each type is also illustrated in Table VIII.

Ascites. There was an incidence of 40 per cent of ascites as compared to the 10 per cent found in cancer of the head. Ascites was typical of the later stage. In 5 cases it was of the chylous type. In every case some other type of metastasis was already evident.

At autopsy ascites was present in 51 per cent of carcinomas involving the body and only in 27 per cent of those involving the head, an incidence somewhat higher than that found clinically.

Thrombosis and peripheral edema. Chart 4 indicates that peripheral edema was noted in 1 case in the initial stage and in 7 cases or 16 per cent, later. In 1 case thrombosis was suspected clinically. In only 2 cases was the edema associated with ascites. This incidence of 16 per cent peripheral edema as compared with 3 per cent for the head may be significant and will be referred to in the discussion.

At autopsy thrombosis of blood vessels was associated with 12 cases or 21 per cent of the carcinomas of the head and with 15 cases, or

33 per cent of the carcinomas of the body. Disseminated thrombosis was not present in the former (head) whereas in the latter (body) 2 such instances were noted. The location of the thrombi were as follows: in the carcinomas of the head the portal circulation was involved in 3 cases, the systemic circulation in 9, in the carcinomas of the body the portal circulation in 5 cases and the systemic in 10. Six additional cases of carcinoma of the pancreas came to autopsy in 1946: 3 involving the head, 3 the body. Thrombosis of blood vessels was present in 3 of these cases (1 carcinoma of the head and 2 carcinomas of the body). In 2 cases (1 head, 1 body) thrombosis was widespread.

Jaundice was present in 3 cases but only in the late stage. In 1 case it was due to extension of the tumor to the head, in another to associated ascending cholangitis, and in a third to metastatic involvement of the liver. These findings were confirmed at autopsy.

ISLET CELL CARCINOMA AND CARCINOMA OF ABERRANT PANCREATIC TISSUE

Two islet cell carcinomas were found in our 104 cases. Both were functioning and widely metastasizing tumors. One originated in aberrant pancreatic tissue in the region of the porta hepatis and was reported from this hospital (1). The other occurred in a 46 year old white female who complained of weight loss, anorexia, periumbilical and back pain with abdominal distention of 1 year's duration when she first sought medical advice. At that time, an enlarged irregular liver and a strongly positive guaiac reaction in the gastric contents were found. It was remarked that during a gastrointestinal x ray examination she suffered a fainting spell. The diagnosis of metastatic carcinoma of the liver was made, primary site unknown. Six months thereafter and 1 month prior to her death she was admitted to our hospital where for the first time fainting spells were recognized as attacks of hypoglycemia. Hepatosplenomegaly, ascites, and metastatic lymph nodes were found. In this case as well as the other quoted the alkaline phosphatase was elevated—there was no jaundice in either case. At autopsy, an islet cell carcinoma of the body and tail of the pancreas with widespread metastases was found.

Three carcinomas in aberrant pancreatic tissue were found in our series 1 of them has been referred to and was classified in Table I as islet cell carcinoma. A second case was a 53 year old male whose illness started 1 year before death with symptoms of 'neuritis' in his right shoulder 2 months later, he began to complain of sharp epigastric pain, unrelated to the digestive cycle. This pain was relieved by sitting up and leaning forward and was not relieved by an ulcer regimen. X ray examination of the gall bladder and intestinal tract was negative. At exploration "an adenocarcinoma of the pancreas with metastases to regional lymph nodes" was diagnosed. Later an epigastric mass and venous thromboses in the upper extremities appeared. At autopsy an adenocarcinoma in aberrant pancreatic tissue at the porta hepatis with extensive metastases was found. A third case was an 80 year old white female, who began losing weight a year prior to her death, and who 9 months later developed signs and symptoms of high intestinal obstruction. The clinical diagnosis entertained was gastric malignancy. At autopsy adenocarcinoma of aberrant pancreatic tissue originating in the second portion of the duodenum was found.

DISCUSSION

From the clinical and pathological data just presented it seems justified to divide carcinomas of the pancreas into two types (1) carcinoma of the head and neck and (2) carcinoma of the body and tail.¹ It is further indicated that there is a much greater relative incidence of carcinoma involving the body than has been heretofore realized, and that the statistics have been unduly weighted by jaundice misdiagnosis and other factors in favor of carcinoma of the head. Of our cases 55 per cent involve the head of the pancreas and 42 per cent the body, 2 cases of carcinoma of aberrant pancreatic tissue and 2 islet cell carcinomas are included among these 104 cases.

Certain differences in sex and age incidence and survival are indicated with respect to involvement of the different areas. In general the incidence of carcinoma of the pancreas is

TABLE VIII.—SITE OF METASTASES AND INVASION NOTED PATHOLOGICALLY IN CARCINOMA OF THE PANCREAS (EXPRESSED IN PERCENTAGE)

twice as high in males as it is in females but this ratio is greater in carcinoma of the head and less in carcinoma of the body. It further appears that the peak age incidence for the head occurs somewhat earlier in life (51 to 60 years) than that for the body (56 to 65 years). As to survival the peak incidence of death in cases of carcinoma of the head occurs between 4 and 6 months while that in carcinoma of the body occurs at 11 months. Shortcircuiting operations for the relief of jaundice in carcinoma of the head appear to prolong life a few months.

In these 104 cases there were wrong clinical diagnoses in 23 per cent of the cancers of the head and in 84 per cent of the cancers of the body indicating the great difficulty in diagnosing the latter. The misdiagnoses encountered in carcinomas of the head were given above, but those entertained in carcinoma of the body were so varied as to defy classification they ranged from a diagnosis of cord tumor or arthritis of the spine, to cancer of the stomach. In not a few cases, functional diag-

¹ Henceforth referred to as carcinoma of the head and carcinoma of the body.

noses were entertained. It is not the intention here to minimize the difficulty but to emphasize it and to focus the attention on the pancreas when vague but suggestive and persistent symptoms of the types described present themselves.

Observations on Signs and Symptoms

Weight loss Rapid weight loss for some reason not entirely clear is distinctly characteristic of cancer of the pancreas. It is reasonable to assume that lesions in an organ concerned with vital intestinal functions such as the splitting and assimilation of foodstuffs would be reflected in a great lowering of the nutritional status. This would seem to be especially applicable to cancer of the head where the entire biliary and pancreatic secretions would be blocked. In our cases it was highest in incidence in the early stage in both types. Rapid weight loss, unaccounted for by other disease such as diabetes, tuberculosis or hyperthyroidism, should arouse a suspicion of pancreatic cancer especially if associated with upper abdominal or back pain. Ingelfinger (18) calls attention to the frequency and importance of weight loss and mentions that this may indicate advanced disease and preclude operability if the body is involved. However for reasons already mentioned, this is not necessarily so in cancer of the head.

Pain Pain was twice as frequent as jaundice as an initial symptom in carcinoma of the head and it increased in incidence as the disease progressed. The classical description of 'painless jaundice' should be modified; it has been perpetuated perhaps because in the differential diagnosis of "obstructive jaundice" the chief interest is in distinguishing between a stone in the cystic or common duct and cancer. Since the former usually produces a severe colic which is excruciating to the extreme, it has been the habit in teaching to relegate the pain of cancer in this region to an insignificant position. If the emphasis were placed more upon the differentiation between the two types rather than the presence or the absence of pain it would be more correct. The pain may not be as immediately intense as the colic of a stone or as prominent a feature as it is in cancer of the body where it is unique, but it

is quite often severe and persistent. It is dull pressing burning aching or boring. It may occasionally simulate biliary or intestinal cramps if it is located in the upper abdomen, usually epigastric and frequently towards the right, and may radiate to the right back and scapular region. Its similarity to ulcer pain and its possible confusion with that condition has been noted (14, 16). The pain does not easily fit into any common pattern and is unrelated as a rule to the digestive cycle.

In carcinoma of the body pain is the outstanding and unique feature of the disease. It is intense, fairly constant, but may be intermittent. It is located deep in the epigastrium or in the back in the lower dorsal or upper lumbar region and often radiates around the lower chest and upper abdomen in girdle-like fashion involving the left hypochondrium and sometimes the lower thoracic segments. It may spread to the epigastric and periumbilical areas. It may be dull boring or sharp and is unrelated to the digestive cycle. The back pain is often the major complaint and is the reason for misdiagnoses such as cord tumor. In its most characteristic form this pain is relieved by sitting up and leaning forward and aggravated by lying down. Thus it is especially troublesome at night and causes the patient in many instances to assume a characteristic position sitting up, bending forward, with lower extremities flexed upon the abdomen in a squatting Indian fashion. Pain is presumably best explained by pressure of the tumor on the celiac plexus, which is intimately related to the posterior surface of the gland. Ransom (25) gives an excellent description of its characteristics in his 16 cases. A study of the neoplastic invasion of nerves and its possible clinical significance in relation to the pain has been made by Drapiewski. Another explanation mentioned for the pain but probably a less likely one is obstruction of the pancreatic duct. The occasional similarity of the pain to that seen in peptic ulcer is possibly explained by ulceration of the tumor through the mucosa of the stomach or duodenum.

Jaundice is not an early sign of carcinoma of the head. Dunphy noted that in 40 per cent of the cases seen at Peter Bent Brigham Hospital there was a delay of several weeks to

several months before jaundice appeared. This agrees with our observations. Actually it is only in the rare case where jaundice alone gives the needed and early clue. In carcinoma of the body, jaundice is absent except late in the disease when it may occur due to extension to the head or metastases.

Gastrointestinal disturbances and obstruction Gastrointestinal complaints of a nonspecific nature figure prominently in the symptomatology of both types of involvement. A good share is attributable to high intestinal obstruction due to pressure on, or invasion of the pyloroduodenal region by the primary tumor; this complication is much more frequent than is realized and is characteristic of both types of involvement, with a similar incidence in each. Low intestinal obstruction is not uncommon in carcinoma of the body.

The occasional incidents of gastrointestinal bleeding, hematemesis or melena or both presumably occur from extension of tumor through the mucosa, either at the primary or metastatic site or from interference with the portal circulation as mentioned previously.

Metastases In some cases metastases cause the presenting signs and symptoms; this occurs 3 times more frequently in carcinoma of the body than in carcinoma of the head. These facts indicate that early stages of pancreatic malignancy may unfortunately be asymptomatic. Wide and diffuse metastatic lesions are typical of carcinoma of the body; relatively infrequent in carcinoma of the head. These differences in spread are possibly due to differences in position and topography of the two sections of the organ, the body being much less encompassed by surrounding structures and rather devoid of covering except for a thin layer of peritoneum on its ventral surface. At postmortem examination 18 per cent of the cases of carcinoma of the head were free of metastases as compared with only 5 per cent for that of the body. It is to be hoped that these cases will henceforth receive the chance for radical surgery and cure.

Disturbances in carbohydrate metabolism The remarkable association between carcinoma of the body and tail and diabetes was already mentioned. Berk, although he does not attempt to differentiate between head and body

or different stages of the disease, reviewed the incidence of 'diabetic' manifestations in the literature. He found glycosuria in 9.4 per cent, hyperglycemia in 19.4 per cent, and impairment of glucose tolerance in 17 per cent of the various series reviewed. He himself examined 9 cases for abnormalities in glucose tolerance, and found them in 7. He therefore considers these tests of great diagnostic importance. Diabetes and disturbances in carbohydrate metabolism are found in a high percentage of cases of carcinoma involving the body and tail. They are infrequent in carcinoma of the head. This is expected since the majority of the islets of Langerhans are located in the body and tail. This difference is well exemplified by our material.

Diabetes has been projected as a predisposing cause of cancer of the pancreas. It has been reported by McKittrick and Root and Marble (23) that 32.4 per cent and 13 per cent respectively of all cancers in the diabetics they studied involved the pancreas, since the comparative figures for the nondiabetic population are 1 to 3 per cent; these figures are striking. Those of McKittrick and Root are based upon 37, and Marble's on 256 malignancies which developed in a large group of diabetic patients. In the former group the onset of diabetes antedated the onset of the pancreatic malignancies by an average of 3.6 years, and in Marble's group by 2.4 years. Marble noted that this interval was shorter in carcinoma of the pancreas than in any of the other malignancies. This latter fact would seem to reinforce the significance of this association. In our series 9 per cent of the patients with carcinoma of the body had pre-existing diabetes. In Berk's own cases without distinction as to type of involvement, there was an incidence of 11.7 per cent and 6.9 per cent was present in a series of 275 cases he reviewed.

Thrombosis and edema It is noted in our material that the incidence of peripheral edema, though this is only presumptive evidence of thrombosis, is much higher in carcinoma of the body than in that of the head. The finding of frequent multiple venous thromboses in cases of carcinoma of the body of the pancreas has been noted by many observers (13, 20, 29). Sproul in 1938 impressed by this associ-

noses were entertained. It is not the intention here to minimize the difficulty but to emphasize it and to focus the attention on the pancreas when vague but suggestive and persistent symptoms of the types described present themselves.

Observations on Signs and Symptoms

Weight loss Rapid weight loss, for some reason not entirely clear is distinctly characteristic of cancer of the pancreas. It is reasonable to assume that lesions in an organ concerned with vital intestinal functions such as the splitting and assimilation of foodstuffs would be reflected in a great lowering of the nutritional status. This would seem to be especially applicable to cancer of the head where the entire biliary and pancreatic secretions would be blocked. In our cases it was highest in incidence in the early stage in both types. Rapid weight loss, unaccounted for by other disease such as diabetes, tuberculosis or hyperthyroidism should arouse a suspicion of pancreatic cancer especially if associated with upper abdominal or back pain. Ingelfinger (18) calls attention to the frequency and importance of weight loss and mentions that this may indicate advanced disease and preclude operability if the body is involved. However for reasons already mentioned, this is not necessarily so in cancer of the head.

Pain Pain was twice as frequent as jaundice as an initial symptom in carcinoma of the head and it increased in incidence as the disease progressed. The classical description of 'painless jaundice' should be modified it has been perpetuated perhaps because in the differential diagnosis of obstructive jaundice the chief interest is in distinguishing between a stone in the cystic or common duct and cancer. Since the former usually produces a severe colic which is excruciating to the extreme it has been the habit in teaching to relegate the pain of cancer in this region to an insignificant position. If the emphasis were placed more upon the differentiation between the two types rather than the presence or the absence of pain, it would be more correct. The pain may not be as immediately intense as the colic of a stone or as prominent a feature as it is in cancer of the body where it is unique, but it

is quite often severe and persistent. It is dull, pressing burning aching or boring. It may occasionally simulate biliary or intestinal cramps. It is located in the upper abdomen, usually epigastric and frequently towards the right, and may radiate to the right back and scapular region. Its similarity to ulcer pain and its possible confusion with that condition has been noted (14-16). The pain does not easily fit into any common pattern and is unrelated as a rule to the digestive cycle.

In carcinoma of the body pain is the outstanding and unique feature of the disease. It is intense, fairly constant, but may be intermittent. It is located deep in the epigastrium or in the back, in the lower dorsal or upper lumbar region, and often radiates around the lower chest and upper abdomen in girdle like fashion involving the left hypochondrium and sometimes the lower thoracic segments. It may spread to the epigastric and periumbilical areas. It may be dull boring or sharp and is unrelated to the digestive cycle. The back pain is often the major complaint and is the reason for misdiagnoses such as cord tumor. Thus it is especially troublesome at night and causes the patient in many instances to assume a characteristic position, sitting up bending forward, with lower extremities flexed upon the abdomen in a squatting Indian fashion. Pain is presumably best explained by pressure of the tumor on the celiac plexus which is intimately related to the posterior surface of the gland. Ransom (15) gives an excellent description of its characteristics in his 16 cases. A study of the neoplastic invasion of nerves and its possible clinical significance in relation to the pain has been made by Drapiewski. Another explanation mentioned for the pain but probably a less likely one, is obstruction of the pancreatic duct. The occasional similarity of the pain to that seen in peptic ulcer is possibly explained by ulceration of the tumor through the mucosa of the stomach or duodenum.

Jaundice is not an early sign of carcinoma of the head. Dunphy noted that in 40 per cent of the cases seen at Peter Bent Brigham Hospital there was a delay of several weeks to

several months before jaundice appeared. This agrees with our observations. Actually it is only in the rare case where jaundice alone gives the needed and early clue. In carcinoma of the body, jaundice is absent except late in the disease when it may occur due to extension to the head or metastases.

Gastrointestinal disturbances and obstruction. Gastrointestinal complaints of a nonspecific nature figure prominently in the symptomatology of both types of involvement. A good share is attributable to high intestinal obstruction due to pressure on or invasion of the pyloroduodenal region by the primary tumor; this complication is much more frequent than is realized and is characteristic of both types of involvement with a similar incidence in each. Low intestinal obstruction is not uncommon in carcinoma of the body.

The occasional incidents of gastrointestinal bleeding, hematemesis or melena or both presumably occur from extension of tumor through the mucosa either at the primary or metastatic site or from interference with the portal circulation, as mentioned previously.

Metastases. In some cases metastases cause the presenting signs and symptoms; this occurs 3 times more frequently in carcinoma of the body than in carcinoma of the head. These facts indicate that early stages of pancreatic malignancy may unfortunately be asymptomatic. Wide and diffuse metastatic lesions are typical of carcinoma of the body, relatively infrequent in carcinoma of the head. These differences in spread are possibly due to differences in position and topography of the two sections of the organ; the body being much less encompassed by surrounding structures and rather devoid of covering except for a thin layer of peritoneum on its ventral surface. At postmortem examination 18 per cent of the cases of carcinoma of the head were free of metastases as compared with only 5 per cent for that of the body. It is to be hoped that these cases will henceforth receive the chance for radical surgery and cure.

Disturbances in carbohydrate metabolism. The remarkable association between carcinoma of the body and tail and diabetes was already mentioned. Berk, although he does not attempt to differentiate between head and body,

or different stages of the disease reviewed the incidence of 'diabetic' manifestations in the literature. He found glycosuria in 9.4 per cent, hyperglycemia in 19.4 per cent and impairment of glucose tolerance in 17 per cent of the various series reviewed. He himself examined 9 cases for abnormalities in glucose tolerance and found them in 7. He therefore considers these tests of great diagnostic importance. Diabetes and disturbances in carbohydrate metabolism are found in a high percentage of cases of carcinoma involving the body and tail. They are infrequent in carcinoma of the head. This is expected since the majority of the islets of Langerhans are located in the body and tail. This difference is well exemplified by our material.

Diabetes has been projected as a predisposing cause of cancer of the pancreas. It has been reported by McKittrick and Root and Marble (23) that 32.4 per cent and 13 per cent, respectively of all cancers in the diabetics they studied involved the pancreas, since the comparative figures for the nondiabetic population are 1 to 3 per cent; these figures are striking. Those of McKittrick and Root are based upon 37 and Marble's on 256 malignancies which developed in a large group of diabetic patients. In the former group the onset of diabetes antedated the onset of the pancreatic malignancies by an average of 3.6 years and in Marble's group by 2.4 years; Marble noted that this interval was shorter in carcinoma of the pancreas than in any of the other malignancies. This latter fact would seem to reinforce the significance of this association. In our series 9 per cent of the patients with carcinoma of the body had pre-existing diabetes; in Berk's own cases without distinction as to type of involvement there was an incidence of 11.7 per cent, and 6.9 per cent was present in a series of 275 cases he reviewed.

Thrombosis and edema. It is noted in our material that the incidence of peripheral edema, though this is only presumptive evidence of thrombosis, is much higher in carcinoma of the body than in that of the head. The finding of frequent multiple venous thromboses in cases of carcinoma of the body of the pancreas has been noted by many observers (13, 20, 29). Sproul in 1938 impressed by this associ-

ation studied the problem and found that of all types of malignancy venous thromboses were most frequently associated with this type of pancreatic involvement. In her series of 49 cases involving the pancreas, she noted an incidence of 9.7 per cent of widely disseminated venous thromboses in tumors involving the head as compared with 31 per cent for those involving the body. She suggested that pancreatic cancers modify in some way the blood clotting mechanism. Kenney arrived at similar conclusions in 51 cases of pancreatic cancer where he found no multiple thromboses in cases involving the head, and 33 per cent in those involving the body. He urges study of all factors concerned with the clotting mechanism in these cases. It should be kept in mind that carcinoma of the body of the pancreas may first manifest itself by peripheral venous thrombosis.

Ascites Ascites was found clinically 4 times as frequently in carcinoma of the body as in carcinoma of the head; in a few it was chylous in character. Since generalized abdominal carcinomatosis and venous thromboses are much more typical of carcinoma of the body this finding is not unexpected.

Steatorrhea and creatorrhea. In this series of cases approximately 7 per cent of the carcinomas of the head were noted clinically to exhibit steatorrhea or creatorrhea or both. However this figure cannot be used as a true indicator of the frequency of disturbances in fat and protein absorption since stool studies were not done in many of the cases. It is probably true that these exist in greater degree in cases of involvement of the head, since here a small lesion may block the pancreatic duct and exclude the secretion from the intestinal tract, whereas massive involvement of the body would be required to reduce the production of pancreatic juice to a comparable degree. Berk reviewed the literature in regard to stool fat content and concluded that less than 10 per cent exhibit steatorrhea.

Aberrant pancreatic tumors Aberrant pancreatic tissue is more common than is generally realized. Faust and Mudgett reported on 370 cases gleaned from the literature, 1 of which was their own. Their analysis of the distribution of aberrant pancreatic tissue showed that

it was most frequently located in the duodenum, 30 per cent, and in lesser degree in other locations, such as stomach, jejunum and ileum. Other unusual sites were mesentery, omentum, gall bladder and spleen. Duff and associates (10) found an incidence of slightly over 1 per cent in 1970 autopsies. It is recognized that both benign and malignant tumors may originate in aberrant pancreatic tissue, and they are often confused with primary tumors in the region involved.

Laboratory aids It is pertinent to remark upon the value of laboratory and x ray studies in the diagnosis of cancer of the pancreas. Defects in carbohydrate metabolism may be present and as already mentioned are more frequent in cancer of the body and tail. Study of the pancreatic enzymes may offer some clues. Johnson and Bockus stated that hyperlipemia was observed in over 50 per cent of 30 patients with pancreatic carcinoma at some stage of the disease. A high value is significant; a low value does not rule out the disease since in the later stages the destruction of pancreatic tissue will reduce the concentration of all the enzymes both in the blood and in the intestine. Serum amylase has also been studied, but the results are more equivocal. Comfort and Osterberg determined both, and they mentioned that serum lipase was elevated in 40 per cent and amylase in only 8 per cent of their cases. Studies of the duodenal secretion of pancreatic enzymes have been made, with and without stimulation by secretin and mecholyl; in some cases, diminished volume of secretion and diminished concentration of both pancreatic enzymes and bicarbonate may be noted. This method of study by duodenal intubation should be useful in differentiating between jaundice due to intracholedochal pathology and that due to involvement of the head of the pancreas by cancer, since in the latter both biliary and pancreatic juices would tend to be diminished. Jaundice may be followed and studied by the usual laboratory procedures. Steatorrhea and creatorrhea, if found, are strongly suggestive of pancreatic disease but a high percentage of negative findings may be expected. Split fats may be found in the intestinal tract without the presence of pancreatic juice either be-

cause of the action of the intestinal juices or the bacterial flora upon the ingested fats. Even in the absence of external pancreatic secretion, practically normal fat digestion and absorption may still go on. Excess fat or nitrogen excretion is best determined by quantitative diet and stool studies. Average values for normal individuals being 1 to 3 grams per day for fecal nitrogen and 10 to 15 grams per day for fecal fat. Figures for fat excretion based upon percentage of dry weight on single stool specimens with patients on an uncontrolled diet are too variable. In pancreatic achylia a marked increase of fecal volume is often found. In 1 case of total pancreatectomy reported by Ricketts and associates, the fecal volume increased from the 150 to 200 grams found normally to 1500 to 1800 grams. Occult blood in the stool is an occasional finding. A moderate anemia irrespective of blood loss, is usually found as is an increase in the sedimentation rate.

X-ray and fluoroscopic examination of the upper gastrointestinal tract may be very helpful. Distortion, displacement and obstruction usually of an extrinsic nature reflected upon the stomach and the duodenum are frequently present. The obstruction and distortion produced by cancer of the head usually involves the pylorus and the entire duodenum, the normal curve of which may be widened and distorted. Cancer of the body usually displaces the stomach upwards and forwards and distorts the pylorus and the proximal duodenum.

A battery of these laboratory and x-ray studies and familiarity with the clinical picture will no doubt enhance the diagnostic accuracy.

Clinical and pathological differences. Since it has been our contention that pancreatic cancer should be divided into two syndromes it would be proper in the final paragraphs of discussion to tabulate these differences briefly in a general fashion. Although many cases show overlapping in clinical symptomatology, Table IX shows schematically the more frequently seen differences.

The clinical differences noted in Table IX were generally confirmed at autopsy. The conspicuous pathological features of carcinoma of the pancreas are as follows: emaciation,

TABLE IX—CLINICAL DIFFERENCES IN INVOLVEMENT OF THE HEAD AND BODY OF THE PANCREAS

Signs and symptoms	Head	Body
Pain	Epigastric and right sided. Less severe and less frequent	Epigastric, left sided and back pain. Severe and almost universally present
Jaundice	Present in most cases	Absent
Diabetes	Infrequent. Sugar tolerance disturbances also infrequent	Diabetes and sugar tolerance disturbances frequent
Ascites	Infrequent	Common
Metastases	Few clinically	Diffuse and widespread
Thrombosis and edema	Not frequent	More common (especially disseminated thrombosis)
Splenomegaly	Rare	More common
Stenorrhoea and crepitation	Occasionally present (10%)	Less frequent
Laboratory findings	Likely to have serum lipase elevation	Less likely to have serum lipase elevation
X-ray defects	Reflected in pyloric area and first, second and third parts of duodenum	Reflected in stomach and first portion of duodenum

ascites, hard tumor invasion of adjacent structures, invasion of blood vessels and a tendency to thrombosis. A distinctive feature of carcinoma of the head is obstruction of the common bile duct with jaundice. Distinctive features of carcinoma of the body are invasion of nerves and a tendency to widespread metastases.

SUMMARY

1. One hundred and four cases of carcinoma of the pancreas were analyzed from the clinical and anatomic points of view.

2. The early and late clinical manifestations were described and correlated with the anatomic findings.

3. The material indicates the advisability of separating the syndromes of pancreatic cancer into 2 main groups: (1) those affecting the head and neck and (2) those affecting the body and tail of the pancreas. The clinical and anatomic differences observed in both groups are described and discussed.

TRANSPLANTATION OF PERONEUS LONGUS TO ANTERIOR TIBIAL INSERTION IN POLIOMYELITIS

ROBERT E. INGERSOLL, M D., Boston Massachusetts

TENDON transfer to replace and substitute for the function of a paralyzed muscle was first performed by Nicoladini in 1882. He attempted to replace a paralyzed tendo achillis by means of the peroneals. Later Lange in 1900 used silk strands to lengthen tendons and Vulpius recommended suture of the transferred tendon to the tendon of the paralyzed muscle. Biesalski in 1910 recommended intrasheath transplantation in order to avoid the complication of adhesions preventing the gliding of tendons which had been a cause of failure in many of the cases reported by Lange and Vulpius. Mayer and Biesalski subsequently reported in their treatise the results of work proving the value of intrasheath transplantation based upon prolonged study of tendon anatomy and physiology.

Transplantation of the peroneus longus as practiced at the New York Orthopedic Dispensary and Hospital follows the method of Biesalski and Mayer. The admonitions of Peabody and Ober should be studied and remembered or tendon transplantation will not be as successful as would otherwise obtain. In a few cases the transplantations have been done by subcutaneous passage of the transplanted tendon without detracting from the result but for the most part the technique has been as follows with the patient under general anesthesia and an Esmarch tourniquet being used: a 1.5 inch incision is made over the lateral aspect of the foot extending from the peroneal tubercle of the os calcis to the base of the fifth metatarsal. The peroneus longus tendon is identified and divided as far distally as possible. (At this point in the operation Mayer advises suture of the distal tendon to the cuboid to act as a check ligament on the first metatarsal and to help prevent dorsal flexion of the first metatarsal segment with resulting dorsal bunion.) The incision is closed temporarily and a second incision 2 inches long is

made over the medial aspect of the foot at the insertion of the anterior tibial tendon. The tendon sheath is opened the tendon split longitudinally and a trap-door hinge distal is created in the medial cuneiform. This incision is then temporarily closed. A third incision 4 inches long is made over the middle third of the anterolateral aspect of the leg. The skin and subcutaneous tissues are dissected medially and laterally from the deep fascia. The superficial sensory branches of the peroneal nerve are identified and preserved. The deep fascia is incised longitudinally over the tendon of the peroneus longus and over the anterior tibial extending slightly proximal to the musculotendinous junction. Short transverse incisions are made at upper and lower ends of the incisions through the deep fascia thus creating two fascial flaps whose far edges are sutured together everting the under surfaces and creating a gliding membrane over which the peroneus longus may be passed. The peroneus is then drawn from the first into the third incision and is passed into the second incision through the sheath of the anterior tibial lying obliquely across the gliding surface made from the fascial flaps. The cut end of the peroneus longus is carried into the trap door in the medial cuneiform with the foot in a corrected attitude and in a position of right angle flexion. In this position it is sutured under physiological tension. The tendon is sutured to bone and to the tendon of the anterior tibial which is pulled proximally under moderate tension. All incisions are then closed in layers. A plaster-of-paris bandage is applied from toes to tibial tubercle maintaining the ankle at 90 degree dorsiflexion.

This study is based on 31 cases of transplantation of the peroneus longus tendon to the anterior tibial insertion in cases of poliomyelitis. The operations were performed at the New York Orthopedic Dispensary and Hospital during the period from July 1 1934

to January 1, 1944. Twenty-one patients have been available for end result study. The follow-up period on those 21 cases ranges from 8 months to 7 years 9 months, with an average follow-up period of 4 years. There were 18 males and 14 females. The age at operation varied from 4 to 35 years with 20 cases in the age group 12 to 19. Of these 21 patients followed a grading of excellent has been given in 33 per cent of good in 38 per cent of fair in 10 per cent, and of poor in 19 per cent. Of the 19 per cent classified poor all 4 cases were dynamic failures and patients either have a residual fixed pronation deformity of the first metatarsal or have had to have ankle fusion performed for complete foot-drop. The 2 cases classified as fair show a residual foot drop gait only with fatigue and a passive first metatarsal drop without an active deforming element. They have no symptoms referable to either residuum. The differentiation between excellent and good, representing a combined percentage of 71 is based principally upon actual strength of the transplanted muscle. Those called excellent have strong transplants in well balanced feet. A good classification is applied to cases in which the transplanted muscle is fair to good in strength and there is no muscle imbalance. These classifications therefore might be criticized to some extent but we were primarily interested in function both of transplanted muscle and of the foot and not solely with actual strength of the transplanted muscle. In addition residual deformity and tendency to recurrent deformity received considerable attention. When residual deformity is absent or present only at rest and when tendency to recurrent deformity has been eliminated, at least a fair rating must be given irrespective of the actual strength of the transplanted muscle.

At the present time, this operation is not done without triple arthrodesis having been performed beforehand. In the past, 8 patients in one of whom the operation was performed on both feet, had transplantation without arthrodesis preceding it. Three of these patients subsequently had to have arthrodeses to correct postoperative varus deformities. One other had an arthrodesis to correct varus but when the tendon was re-

transplanted to a more lateral position the result was a failure and ankle fusion was performed for foot-drop. None of the patients who had arthrodeses first developed subsequent varus deformities, a factor which could be taken to signify an increase in strength in the anterior tibial secondary to re-enforcement by a well functioning transplant. We have had some misgivings about doing this operation in patients with some residual power in the anterior tibial because it has been noted that occasionally the anterior tibial increases in strength in the patients who are treated by transplantation of the extensor digitorum longus to the mid foot. It was feared that this increase in strength might occur in these cases and cause a varus deformity. The peroneus longus transplantation is never done, therefore, when any amount of power remains in the anterior tibial. Since the anterior tibial and peroneus longus muscles are antagonistic in their action upon the first metatarsal segment re-enforcement of the former by transplantation of the latter is definitely contraindicated. The relative strength of both extensor and flexor hallucis longus muscles should also be considered. One patient now presents a dorsal bunion and dorsally flexed first metatarsal segment following transplantation of the peroneus longus in the presence of a strong flexor hallucis longus and a paralyzed extensor proprius hallucis.

The postoperative fixation period varied from 3 to 10 weeks with a mean of 5 weeks. Our opinion about this part of the treatment has been revised. We now feel that with anchorage of the transplanted muscle into bone we can safely begin 'setting' exercises at 3 weeks after operation. Patients have their plaster boots bivalved and should wear the posterior shell at all times. Exercises are given with the shell in place and are carried out daily. At the end of an additional 2 weeks they should be able actively to dorsiflex the foot easily from the position of right angle dorsiflexion. They are then ready for ambulant activity in a brace.

In a paralytic foot with absent or very weak tibialis muscles the fundamental deformity is valgus, either static or dynamic or both. More important than this, however is the forefoot

cannot be done with absolute certainty. Observation of a foot in active eversion and testing the resistance of a foot in this position is the first step. Attempting passive dorsal flexion of the first metatarsal segment plus palpation of the individual tendons proximal and posterior to the lateral malleolus yields additional information to one who is accustomed to testing and grading muscle strength. The remaining extensor muscle strength should also receive close consideration and in the absence of good strength in the extensor proprius hallucis and extensor digitorum longus, transplantation of both peroneals should be the chosen procedure. This latter muscle, namely the peroneus brevis, being unsuitable for intrasheath transplantation can be so placed as to effect a lateral balance of power in the previously stabilized foot.

The postoperative management of these cases especially of the more recently performed operations have borne out the importance of proper postoperative training. Any transplant is not as strong as the normal muscle and therefore should be protected by suitable apparatus and strengthened by careful graded exercises. This latter should be continued until one is satisfied that the transplanted muscle is capable of performing the work required of it. Three patients seen at the New York Orthopedic Hospital Outpatient Clinic and 2 patients seen elsewhere have been noted to have little demonstrable power following discharge from the hospital—this meant usually 5 weeks of fixation, 2 to 4 weeks of physical therapy and exercises in the hospital and at home for a varying period. On examination no response could be elicited in the transplanted muscle except with cajoling and considerable effort on the part of the patient and examiner. With an intensive program of carefully planned physical therapy within 3 weeks function was markedly improved. Two methods of exercising these transplanted muscles have been used: (1) active dorsiflexion exercises until peroneus comes into action; (2) graded instruction and use of peroneus as an evorter along with exercises for dorsiflexion. The patient attempts eversion and dorsiflexion as a combined measure. This seems to call upon the peroneus longus as it would have

functioned in its original position as an evorter. Since the insertion has been changed one readily established an association between dorsiflexion and eversion resulting in peroneus longus function as a dorsiflexor because of its altered insertion. In simple dorsiflexion exercises however no active effort is made by the peroneus and re-education fails. The method embodying a combined motion seems the more logical.

Since the re-establishment of function in this transplant is difficult and painstaking in recent cases patients have been fitted with ankle braces. These serve a dual purpose acting to protect the transplanted muscle from postural stretch and from the dynamic influence of a strong calf. In cases in which heel cord lengthening has been done brace protection has been routine at the New York Orthopedic Hospital. The addition of another catch to the ankle brace serves to protect the transplanted muscle as well. The re-education of those patients who have had the benefit of brace protection has been more rapid.

In the consideration of treatment of paralytic valgus differentiation of the static from the dynamic deformity or from a combination of both must be made. It is in the purely static type of deformity that stabilization alone yields excellent results. A combination of the two types of deformity requires usually both stabilization and transplantation of tendons. Without the latter procedure, recurrence of deformity even in the presence of a firm bony fusion of the subtalar and midtarsal joints is the result. At the same time one must realize that removal of the deforming force of an unopposed peroneus longus even though the resulting strength of the transplant is not good, is still to be considered a good result since we have produced a foot stabilized in a good attitude for function without a deforming tendency. This might be said to be a good negative result as opposed to a good positive result in which the transplanted muscle is strong. This fact of course, must be considered in studying the end result. It is in this type of foot that the patient may note no remarkable change. The transplant, however, must be considered at least fair by reason of the negative result.

Fig. 1. left. Active dorsiflexion of foot in which peroneus longus is overactive and anterior tibial is paralyzed, showing the pronation of first metatarsal segment.

Fig. 2. Pronation of first metatarsal segment as seen from lateral side of foot. Muscle imbalance clearly demonstrated here.

The equinus element of this deformity is variable depending upon the extent of the extensor muscle paralysis and the strength of the calf. Upon this will depend the success of transplantation of the peroneus longus. The presence of marked extensor paralysis militates against the success of the simple transplant. The presence of calf contracture also defeats the transplant for two reasons (1) increased tension in the transplanted muscle which becomes greater with the contracture of the calf (2) a dynamic as well as static influence in presence of marked extensor weakness and a strong calf.

The transplant failed to function in 4 cases and these 4 patients had marked calf contracture. Five patients had a calcaneal tendon lengthening at the time of transplantation and in only one was the strength of the trans-

Fig. 3. Two postoperative views of same foot after triple arthrodesis and peroneus longus transplant showing restoration of muscle balance and active dorsiflexion without dynamic deformity.

planted muscle not good. The other 4 had very strong active transplanted muscles. Most of the patients with residual calf contracture of 10 degrees or more showed less actual strength in the transplanted muscle than was noted in the group without calf contracture. Some of these had no treatment of the heel cord shortening because it exerted a beneficial effect upon a weakness at the knee. Here, of course a negative result was accepted in order to preserve the function of the extremity as a whole. If however the knee is stable of itself calf contracture should be carefully considered and treated at the time of transplantation. Lengthening of the tendo achillis adds much to the operative result and does not increase the surgical risk.

One may question the judgment in cases selected for transplantation in which calf weakness plus a weakness of dorsiflexion obtained with or without a sufficient quadriceps weakness to make for an instability at the knee. At least 7 patients were discovered with this dis-

Fig. 4. Preoperative roentgenogram showing lateral view of foot at rest. The first metatarsal pronation is clearly indicated.

Fig. 5. Postoperative roentgenogram showing correction of first metatarsal pronation by triple arthrodesis and first metatarsal osteotomy as indicated by arrow.

crepancy of whom one required after operation stabilization of the knee by a brace. Two other patients felt they were no better because the calcaneus element of the limp was not improved. Those patients with sufficient calf power to limp only slightly at a slow gait noted real improvement when drop-foot was eliminated but the group with a loss of calf strength sufficient to make an unsightly calcaneal limp were disappointed with the results of their operations. This group and those with knee instabilities might have been better with pantalar arthrodesis and a consequent functional take-off from the ball of the foot. These patients, of course do not have the potato-foot deformity usually seen in severe calcaneus and although the entire extremity requires further stabilizing procedures a definite tendency to recurrent deformity has been removed and the function of the foot has been improved thereby. Since ankle fusion is undertaken usually at a later age it behooves us to establish lateral muscle balance without deforming tendency to a foot which has already shown progressive deformity. We can then await a definite demonstration of functional inadequacy of the extremity before proceeding with additional stabilizing surgery. Even though ankle fusion may be necessary in the future this latter procedure does not alter the condition of imbalance and will not prevent redevelopment of deformity. These patients will still develop the huge callosity under the first metatarsal head with symptoms from this. They will also show a progressive recurrence of a pronation deformity of the forefoot.

The alternate procedures available to us in cases requiring ankle fusion are resection of a portion of the peroneus longus tendoo or tenotomy to obtain the negative result without attempting to gain the 'positive' result.

These procedures have not been performed at this hospital. When this is done however one must be absolutely certain that the patient cannot get along without a brace and without ankle fusion. Many times this may be a moot question. Transplant followed by a long period of observation therefore, makes itself the procedure of choice. Certainly if we can leave the patient with a stable extremity in which ankle motion still obtains, it is incumbent upon us to do just this.

The following recommendations seem indicated in treatment of these patients

- 1 Careful preoperative muscle grading
- 2 Attention to calf contracture.
- 3 Stabilization of the foot preoperatively correcting all fixed deformity at this time
4. Improvement in the technique of transplantation
- 5 Shortening of the period of absolute fixation to 3 weeks.
- 6 Postoperative brace fixation until the transplant demonstrates maximum obtainable power
- 7 Careful postoperative physical therapy
- 8 The end result may be a good 'negative' result in which progressive deformity has been checked or a good 'positive' result in which the transplanted muscle is strong and the foot well balanced

TUMORS OF THE BREAST

Preoperative Roentgenography

J GERSHON COHEN M D., and PHILIP J HODES M D Philadelphia, Pennsylvania

MEDICAL propaganda has been effective in bringing more patients to the doctor early in the course of their disease. This opportunity for the recognition of early tumors is a challenge to the medical profession that must be met by improvement in diagnostic methods. Concerning the breast, except for a recent suggestion that radioactive isotopes (11) may be helpful in the early diagnosis of cancer, nothing new has been developed since the introduction of transillumination (2) and roentgenography (3, 9, 10, 12, 13). Until a definite method of diagnosis becomes available roentgenography would seem to merit better appreciation as an aid in the clinical diagnosis of mammary disease.

GENERAL CONSIDERATIONS

The roentgen diagnosis of breast abnormalities is extremely difficult. It requires meticulous technique and considerable experience. In no way is it a substitute for a careful history and a painstaking physical examination.

A complete roentgen study comprises examination of both breasts and axillae. This makes possible detection of metastatic lymph nodes as well as the primary lesions in the breast. Whereas metastatic axillary nodes are often felt with ease many that remain unrecognized by palpation can be demonstrated roentgenographically. Metastatic malignant axillary nodes often are sharply defined and stand out more clearly than those enlarged from other causes.

In the breasts, the skin has a different density than the subcutaneous fat. The veins traversing the subcutaneous and fatty portions of the breast are demonstrated easily. The interfascial plane between the base of the breast and the pectoral muscles can be disclosed. Elements of the suspensory ligament which divide the subcutaneous layer cast a dif-

ferent shadow in the roentgenogram than does the surrounding lipid tissue. Fat is an excellent contrast medium for the glandular and stromal structure of the breast so that the more fat in a breast the easier it is to demonstrate mammary structure. This is fortuitous since it is the fat breast which offers the greatest difficulty to clinical examination.

The uncertainty presented by abnormal roentgen mammary patterns is not so much their detection as their interpretation. As to detection obvious limitations are apparent the most important being the earliest stage of cancer which can be appraised. When is cancer 'early' and what criteria for diagnosis at this early stage can be found acceptable to pathologist, clinician and roentgenologist alike? A cancer cell *in situ* may be as much a cancer cell as one out of bounds. Not only cannot pathologists agree on this but clinicians too generally will not allow that a cancer cell *in situ* comes under the heading of disease. There are those who maintain—and not without reason—that a cancer cell which has not broken through its normal confines cannot be classified as disease. It is within the realm of possibility that many initially formed cancer cells while still *in situ* are either desquamated like normal cells or destroyed by the body's protective mechanisms before they break through their limiting membranes. Since the demonstration of cancer cells even in rather large cell aggregates is most difficult for the roentgenologist except in fatty breasts, it concerns him little if the pathologist argues about cancer cells *in situ* as the first stage of cancer. This stage of the disease is far earlier than can be detected by any roentgen means so far devised. It therefore, follows that the earliest changes identified roentgenographically would be those modifying the mammary architecture as the result of infiltration and proliferation by large cell masses.

In the compact nonfatty breast of the adolescent and the thin nonlactating breast of the adult normal as well as abnormal infiltration can occur on a large scale without roentgen manifestations. This is complicated manyfold by the wide variations in breast patterns that normally exist among breasts in different healthy women. To this must be added the difficulties which arise because of the physiologic changes that occur in breasts of the same woman during adolescence, the menstrual cycle, the menopause and in the postclimacteric period. In spite of this pleomorphism it is encouraging to note how often early abnormal changes in mammary architecture can be appreciated by roentgenologists proficient in this field.

The next hurdle, however, is more difficult. What use is the recognition of abnormal shadows in the breast if their meaning is not discernible? To this end thorough familiarity with the physiology of the breast, the symptoms of its diseases as well as a good history and physical examination are of paramount importance. Even then unequivocal conclusions can be reached in but a small proportion of cases (4).

The greatest satisfaction in routine roentgenography of breasts for the diagnosis of early cancer stems from that small group of cases, possibly less than 10 per cent, in which both the clinical examination and transillumination have failed. This group includes primarily patients with large fat breasts in which the glandular and stromal structures are recognized easily and where localized infiltrates out of bounds in the fat tissues become apparent readily to the roentgenologist. In such instances the surgeon is furnished crucial information of which he may not have been aware. This is always a greater triumph for the roentgen technique than the mere confirmation of the presence of a tumor or nodule previously detected by the patient or the clinician (Fig. 1).

While in rare instances radiologists discover a tumor mass lying deep in the breast that is protected from manual palpation by a thick pad of overlying mammary or lipoid tissue, the majority of roentgen examinations merely confirm the presence of abnormal nodules or

infiltrates found clinically. This confirmatory evidence, however, has distinct value. In addition to delineating the pathological structures with a preciseness not possible by clinical examination, a permanent record is secured which can be used for comparative studies during the progress of the disease (Fig. 2).

Various methods have been used for visualizing the ductal system of the breasts with opaque media. These have made possible the recognition and biopsy of intraductal abnormalities, but the methods are painful and tedious. They require a great deal of skill and experience and carry the constant threat of infection. Only when a positive microscopic diagnosis of malignancy is established can these procedures be regarded as reliable (6, 7, 8). Pneumomammography also has been used by radiologists and surgeons in an effort to increase their diagnostic acumen. Air, oxygen or carbon dioxide injected interstitially under pressure serve as adequate contrast substances, but the value of the procedure has yet to be established (5).

THE BREAST WITH A SINGLE TUMOR

When a single lump in the breast is found by the patient or her physician, the prime objective of the roentgenologist is its visualization. When the patient states that the lump varies in size from time to time, the breast can be checked at intervals when the patient believes these changes to be most pronounced. Confirmation of these changes is fairly good evidence of a nonmalignant lesion, one which may be due to trauma, infection or more usually a functional endocrine disturbance. On the other hand, when there is evidence that the lump has been enlarging progressively or that the nipple or skin has become retracted, one examination will suffice. No matter what is observed in the film, the lesion is apt to be malignant. A detailed account of the manner in which a nodule has grown, therefore, is extremely important.

In the roentgenogram, the lack of sharpness of the margins and the irregularities of contour are the crucial findings that differentiate the malignant from the benign processes. Benign lesions usually have spherical smooth outlines (Fig. 3). It cannot be denied that a

Fig 1a

Fig 2a.

Fig 1b

Fig 2b.

Fig 1. Anaplastic carcinoma. A lump was felt in the opposite breast by the patient 4 days before medical consultation. The x-ray films disclosed nothing abnormal but in the symptomatic breast, an irregularly outlined mass about 1.5 centimeters in diameter was visible in the roentgenogram, a, and the diagnosis of probable malignancy was based on the irregularity of the margins of the lesion. The microscopic studies, b, revealed the presence of an anaplastic carcinoma.

single discrete movable and circumscribed nodule with no retraction of the skin even in a young woman may prove to be a highly ma-

Fig 2. Scirrhous carcinoma. The opposite breast had been removed 5 years previously after a diagnosis of carcinoma had been established. The patient noted a small lump in this breast 1 week before the x-ray examination, a. The lesion was demonstrated easily because of its location in the fatty tissues. The irregularity of its margins suggested malignancy which was confirmed by microscopic examination, b, of the tissue as scirrhous carcinoma.

lignant cancer. It is also true that a ductal carcinoma cannot be differentiated from a fibroadenoma if there has been no effect on the nip-

ple or overlying skin. Nor can a carcinomatous infiltration which has undergone cystic degeneration be differentiated from a benign cyst merely by the sharpness and smoothness of the outline and contour. The final diagnosis in such cases rests on the findings of microscopical study of the section (1). Irregularly outlined lesions caused by localized benign nodularity must be distinguished from a single discrete malignant tumor. A collection of cysts in cystic mastitis, early multiple fibroadenomas and papillomas cannot be differentiated easily from a localized nodular cancer. The roentgenographic method offers one the opportunity of determining malignancy by studying the outlines of a tumor but the diagnosis is often inconclusive. A suspicious carcinomatous infiltration might then be checked by re-examination later. Here again care in eliciting a careful history can be of the utmost importance (Fig. 4).

THE MULTINODULAR BREAST

The difficulties attending the proper roentgen interpretation of a single mammary tumor are compounded in the multinodular breast. Since there exists a diffuse form of cancer which can mimic a benign multinodular infiltration the greater chances of diagnostic error must be recognized.

In the fat pendulous breast the branches of the suspensory ligament which insert into the skin may become quite dense and divide the subcutaneous fat layer into lobules. This type of false multinodularity is recognized easily in the roentgenogram if not by palpation.

In thin subjects with little or no fat a diffuse nodularity can be palpated which is due to extension of glandular elements into the bases of the branches of the ligaments suspensoria. Since the average breast is covered by a layer of fat ranging from 1 to 4 centimeters in thickness this nodularity is demonstrated often more easily roentgenographically than by palpation.

Another form of multinodularity is encountered in women who have borne children. After lactation involutional atrophy of the acini always is greater than that of the ducts which then must become convoluted to accommodate themselves to the smaller area of

atrophied breast. This produces a diffuse nodularity and is another form which can be seen usually in roentgenograms when not appreciated by palpation.

The multinodularity caused by cystic mastitis does not have the symmetrical distribution that characterizes the breast lesions already mentioned. In this condition the nodules usually are not the same size and their distribution is irregular. Cysts must be many millimeters in diameter before they can be demonstrated by roentgen methods. Large cysts are readily discernible in fat breasts even when they escape palpation.

Finally some rare forms of carcinoma produce a diffuse nodularity which is usually either bilateral or symmetrical but which almost always involves the skin retracting or distorting it by the pull of the infiltrations into the bases of the suspensory ligament. These changes can be seen by inspection usually easier than in the x ray film.

THE RADIOLOGIC AND SURGICAL RELATIONSHIP

Until some specific test is developed for the diagnosis of early carcinoma of the breast, every diagnostic procedure now available should be employed. Among these, the roentgenographic approach cannot be omitted even though its field of usefulness is limited. Not only would it seem advisable that its use be part of every routine examination of the breast, but also that its use should be part of every preoperative procedure. This is particularly true of the survey examination of the lungs and the skeleton. Those with experience are aware how often the absence of mammary findings is associated with the presence of metastatic regional lymph nodes or more distant metastatic foci elsewhere in the body. The radiologist not infrequently wonders whether the bone metastases he finds some months after mastectomy were present before the operation. There is a small but well recognized group of highly malignant carcinomas of the breast in which the first sign of the disease may be caused by a metastatic deposit. These deposits may be palpated in the axillary nodes or revealed only after x ray examination of the bones. A spontaneous fracture of a bone or

Fig. 3. Cystic mastitis. This patient felt a lump in the right breast 3 weeks after delivery. Moderate irregular multinodularity was palpable in both breasts and a smoothly contoured mass in the right breast about 5 centimeters in diameter was visible in the roentgenogram, a. This mass was removed and the microscopic examination, b, of the tissues revealed the presence of cystic mastitis.

Fig. 4. Adenocarcinoma. This patient felt a lump in her breast over a period of several weeks with slight increase of its size. Roentgenologic examination a, disclosed a small irregular mass with no retraction of the skin. A mastectomy was carried out and the microscopic study b, which was made of the tissues revealed the presence of an adenocarcinoma.

pain in the spine due to metastasis may occur as the initial sign in rare instances

In cases in which a doubtful appraisal of a mammary mass has resulted after all diagnos-

tic measures have been exhausted and it is unfortunate that this occurs in many cases a local exploratory operation or mastectomy would seem indicated without delay. While

the radiologist may have found one or more lesions that were not recognized by physical examination and while by their shape and contour he might have been led in his opinion to favor the diagnosis of a benign process it must be conceded that the chances of error are greater than the dictates of safety allow. Under such circumstances, prompt biopsy cannot be avoided. If the consensus favors a benign lesion simple biopsy usually is safe and sufficient. If the suspicion of malignancy exists then frozen section with arrangements and permission for proper surgical management cannot be delayed.

SUMMARY

Roentgenography of the breast has much to recommend its routine use in the diagnosis of mammary disease especially in the diagnosis of early malignant processes. Small malignant lesions in fat breasts often can be demonstrated when their presence is not otherwise suspected. Abnormalities and other diseases of the breast also can be studied and while there are limitations to accurate diagnosis these limitations can be reduced by better acquaintance with the roentgen examination.

The malignancy or benignancy of a growth occasionally can be determined by its roentgenographic appearance but when this is impossible the surgeon is furnished additional data by which to direct his surgical procedure. A survey x ray examination of the chest and skeleton might well be recommended before operation for all patients suspected of having malignant disease.

NEUROVASCULAR COMPLICATIONS FROM MALPOSITION ON THE OPERATING TABLE

H. C. SLOCUM M.D., K. C. O'NEAL, M.D. and C. R. ALLEN Ph.D. M.D. Galveston Texas

THE sequelae of malposition on the operating table are often of serious consequence. Previously, we have discussed respiratory and circulatory embarrassment resulting from improper positions on the operating table (10). This paper is devoted to some of the neurovascular injuries which occur either with, or independently of the other physiological disturbances.

In most cases neurovascular injuries are preventable. Although such injuries are relatively infrequent they occur more often than is suspected. Awareness and foresight in the prevention of these complications is preferable to therapy however effective after the injuries occur.

Nerve paralyses following anesthesia were observed shortly after the advent of ether narcosis (1-6) and were attributed by some to the toxic effects of the anesthetic agent (7). It was soon learned, however, that these injuries were associated with the position of the patient on the operating table.

Although numerous articles were written about the year of 1900 with adequate and detailed explanations of the etiology these preventable injuries have continued to occur.

The principal factor in such injuries is ischemia resulting from stretching or pressure on the nerve (3-4). The experimental work of Denny Brown demonstrates the mechanics and the pathology of this trauma. He points out that pressure for even a few minutes may cause impaired nerve function. The effects of pressure on nerve function are graded as of four degrees: (1) no effect; (2) paralysis with rapid complete recovery on release of pressure; (3) paralysis with delayed recovery without degeneration; and (4) complete anatomic lesion with degenerative phenomena.

During anesthesia if muscle tonus is reduced a patient becomes more susceptible to

the effects of unphysiologic positions. With perceptive powers no longer intact he is unable to complain of postural insults which normally he would not tolerate.

Under these conditions, trauma to the nerves or vascular structures may occur and the damage not be discovered until the patient has responded from the anesthetic. Unless the injury is pronounced the impairment of function may not even then be noted without careful postoperative observation. Minor dysfunctions are often masked by heavy postoperative sedation.

The brachial plexus is quite vulnerable to damage from malposition. Clausen has written a detailed account of the anatomical relations of the plexus and its surrounding structures. He evaluates the effect of various positions on the nerve trunks. Injury to the plexus is ascribed to any of several factors which increase the tension in the nerves by increasing the distance between their points of fixation. These factors are: (1) stretching of the nerves over the arch formed by the tendinous attachment of the pectoralis minor to the coracoid process; (2) depression of the clavicle into the retroclavicular space; (3) lateral deviation and extension of the patient's head; (4) stretching of the plexus over the prominence formed by the head of the humerus with the arm in external rotation, abduction and extension; and (5) compression between the clavicle and the first rib. Congenital anomalies such as cervical ribs or anomalous derivation of the plexus may make the nerves more vulnerable (2).

The abnormal relations as just described may be produced by hyperextending the arm on a board as is sometimes done for axillary surgery for infusions or to make room for the surgeon's assistant. If a steep Trendelenburg position with inadequate or poorly placed shoulder braces is employed the patient may be suspended by his wrists thereby stretching

Fig. 1. Anatomical relations of the brachial plexus. Inset, Trendelenburg position showing misplacement of the right shoulder brace as the result of the extension of the arm on an arm board.

the plexus down over the first rib. Injury may also occur from the shoulder brace itself when it is not placed over the bony acromioclavicular joint and is allowed to press on the soft structures in the supraclavicular space. Brachial plexus paralyses have been observed more frequently since the advent of curare. With this additional loss of muscle tonus, misplaced shoulder braces are more likely to compress the nerve trunks of the plexus.

Damage to the brachial plexus may be evidenced in motor and sensory impairment of the arm and shoulder girdle. Instances of Horner's syndrome resulting from injury to the lower roots of the plexus have also been reported (2, 6).

Figure 1 inset shows a patient in steep Trendelenburg position. The right arm has been extended on an arm board for an infusion without the shoulder brace on that side being removed. When the arm is extended from the side to this position while the patient is resting primarily on the shoulder braces the arm acts as a lever and moves the patient to that

side of the table. When this is done the brace no longer presses against the bony acromioclavicular portion of the shoulder but rests against the trapezius muscle and the brachial plexus. Figure 1 gives a diagrammatic conception of the relation of the brachial plexus to its surrounding structures. The weight of the body of the patient resting upon the brachial nerves by pressure or stretching may result in malfunction of the arm on that side. Paralyses occurred in one such instance following a hysterectomy and was noted on the evening of the operative day. The condition remained for 3 days and then gradually improved so that normal function had apparently returned by the ninth postoperative day. In a similar case function in the arm was still impaired when the patient left the hospital 6 weeks later. Wood describes a case with bilateral brachial palsy lasting for 1 year after the operation (12).

The radial, ulnar and median nerves are vulnerable to trauma as they traverse the brachium (Fig. 2). In this illustration it can

Fig. 2 Schematic presentation of nerves subject to injury. Inset, Improper position of patient on operating table causing pressure against the inner aspect of arm.

Fig. 3 Diagram of structures vulnerable to pressure from leg braces. Inset, Lithotomy position showing braces pressing against the leg.

be seen that if the arm hangs over the edge of the operating table as in Figure 2, inset the nerve is likely to be compressed between the humerus and the edge of the table. If the surgical assistant leans against the arm, the pressure is augmented and damage to the nerve is likely to occur. Instances of ulnar paralysis have occurred in emaciated patients due to pressure of the arm on the bed (11).

During the course of a pelvic operation with the patient in a moderate Trendelenburg position the right arm was extended on a board for infusion. During the operation this arm was pushed into hyperabduction to make room for an assistant. In doing so the posterior aspect of the arm was forced against the anesthetic screen which was fastened to the edge of the table. Since the arm was beneath

Fig. 4. Diagram of structures subject to injury in the pressure areas illustrated in inset. Inset shows compression of leg between hard knee roll and tight strap.

the drapes this pressure was not noticed until the end of the operation. After operation the patient noticed a weakness of the right arm. Examination revealed a wrist drop and sensory changes indicative of a radial nerve paralysis. This dysfunction persisted 1 month after the operation.

Foot-drop from paralysis of the common peroneal nerve and paresthesia due to damage of the saphenous nerve may be attributed to the lithotomy position. When the metal braces which hold the stirrups are extended (Figure 3 and 3 inset) undue pressure may be placed on the saphenous nerve.

In 1 instance 6 hours following a transurethral resection the patient complained of a numb feeling on the inner side of his right leg. It had been noted at the end of the operation that the metal brace for the stirrup had left a pressure mark on the inner surface of the leg. The nerve function returned in a few days.

The leg braces on obstetrical tables are usually constructed in the form of a curved metal support and the leg rests over this with pressure in the popliteal fossa. Unless these metal leg rests are sufficiently padded there is danger of injury to the common peroneal

nerve as well as to the vascular structures in the popliteal fossa. Tourniquets applied with too much pressure for too long a period (5) or hard knee rolls as are sometimes used in positioning patients on the operating table (Figure 4 and 4 inset) may produce similar injuries.

Coincident with the nerve injuries described there may be peripheral vascular damage.

When the patient's arm is hyperabducted as is described in injuries to the brachial plexus, the subclavian or axillary arteries may be compressed and occluded. Wright in reporting a study of 150 young adults revealed that a pulse of the arm can be obliterated in the position of hyperabduction in approximately 83 per cent of all normal persons. The patients described in his series developed their syndromes for the most part as a result of sleeping with the arms in a hyperabducted position. In one instance this progressed to the point of gangrene of the fingers.

Another vascular complication is venous thrombosis resulting from stasis when braces, padding or straps occlude the superficial veins (Fig. 4 and inset). One patient developed a venous thrombosis of the superficial veins of the thigh because the strap which held the patient in position was secured too tightly.

Fig. 5 Pressure on the right eye resulting from the improper position of the head rest. Inset, Retinal thrombosis resulting from pressure on the eye.

An instance of vascular damage of particular significance because of its complications occurred during a neurosurgical procedure for section of the fifth cranial nerve. A Bailey head rest (Fig. 5) was employed. During the procedure the head was pushed to one side and the forehead piece slipped causing pressure on the right eye. This extraocular tension plus the lowered blood pressure due to the effects of gravity and blood loss were undoubtedly responsible for the retinal thrombus (Fig. 5 inset) which was discovered on postoperative examination. During the first day after the operation the patient could not distinguish light from dark. On the second postoperative day she could see objects and detect color. There was no further improvement. The gravity of this picture may be enhanced when it is mentioned that the patient had sight in only this eye prior to the operation.

The foregoing instances which have been cited are not unique. The literature contains numerous examples but in relation to the

number of anesthetics given each year, the incidence of occurrence is small. The fact that these injuries are preventable makes even a few regrettable.

The treatment of nerve injuries of this type is principally physiotherapy. The majority recover completely although in some a permanent residual dysfunction remains. The vascular injuries may respond to physiotherapy. In many instances sympathetic blocks are valuable. Again complete recovery cannot be assured.

Prevention of injuries requires an awareness of the potential dangers of the various positions. There is no substitute for good judgment in considering the requirements of each individual case. In those positions where strain or pressure on the neurovascular system of the patient is obvious or probable the position should be altered until both anesthesiologist and surgeon are satisfied that the patient is adequately protected.

Points of obvious pressure should be properly padded, and when straps are used to

hold the patient in position they should be examined to see that they are not too tight.

Both the anesthetist and the surgeon should be constantly alert to the effects of malposition.

VARIOUS TYPES OF DIAPHRAGMATIC HERNIA TREATED SURGICALLY

Report of 430 Cases

STUART W. HARRINGTON, M.D., F.A.C.S., Rochester, Minnesota

DIAPHRAGMATIC hernia is an inclusive term and is commonly used to designate any condition in which the abdominal contents protrude into the thoracic cavity through an abnormal opening in the diaphragm. These abnormal openings may be attributable to congenital structural deficiencies of the diaphragm or they may be caused by traumatic rupture or inflammatory necrosis of the normal diaphragm. All true hernias have a sac as one of their component parts so that many conditions commonly included under this term but which do not have hernial sacs would more properly be termed eviscerations or 'false hernias'. The occurrence of herniation of abdominal viscera through the diaphragm is relatively uncommon when compared with the frequency of herniations through the abdominal wall but more different kinds of hernia occur through the diaphragm than through the other walls which encase the abdominal contents. The reason for the different types of diaphragmatic hernias is the unusual embryologic formation of the diaphragm which makes for weak parts through which these hernias may occur.

The formation of the diaphragm from embryonic structures is a highly complex process because the muscular elements of the diaphragm are derived from several sources. The anterior lateral and central parts which comprise the greater portion of the diaphragm in the adult person are formed from the transverse septum and fused ventral mesentery. The remaining posterolateral portion is formed by the fusion of the dorsal mesentery and the mesoderm derived from the receding wolffian body with the pleuroperitoneal membrane derived from the pulmonary ridge. It is difficult to determine the exact amount of

muscle tissue that is derived from each of these structures since considerable variation probably occurs during the process but it is likely that the dorsal mesentery forms the posterior and central portions which contain the esophageal opening. The mesodermal cells form the receding wolffian body from the right and left crura. The pleuroperitoneal membrane grows ventrally and by fusion with the transverse septum closes the remaining opening which may be designated as the pleuroperitoneal hiatus between the peritoneal celom and the pleural celom. This completes the formation of the posterolateral portion of the diaphragm (Fig. 1).

Failure of fusion or failure of proper deposition of the mesoderm at any one of these adjacent points of union may result in congenital continuity of the pleural and peritoneal cavities or a congenitally weak portion in the diaphragm at any of these points. Consequently, from an embryologic standpoint weak portions might be expected to appear at the points of fusion of these different structures. These portions are situated dorsolaterally at the fissura pleuroperitonealis which when covered with peritoneal and pleural membranes is termed the foramen of Bochdalek and also through the outer crus of the diaphragm and through the esophageal opening. The dome of the diaphragm embryologically is not a fused region. Herniation through the dome therefore cannot be explained on the basis of weak points of fusion. Such a hernia may be the result of excessive degeneration of the muscle in the formation of the central tendon or of some pathologic condition. Unilateral absence of the diaphragm probably is the result of the failure of development of the pleuroperitoneal membrane which usually is found as a narrow ridge of tissue along the posterior wall of the thorax.

From the Division of Surgery, Mayo Clinic.

CLASSIFICATION OF DIAPHRAGMATIC HERNIA

There are numerous classifications of diaphragmatic hernia which are based on the embryologic and etiologic aspects, pathologic anatomy, the site of the opening in the diaphragm, the presence or absence of a sac, the contents of the hernia and other factors. It is difficult or impossible to make use of most of these classifications after clinical examination accordingly many of them are of little clinical value. The most accurate determination of the various types of diaphragmatic hernia is that obtained at the time of operation.

From a clinical and surgical standpoint the history of an injury is helpful in establishment of the diagnosis and in determination of the type, urgency and prognosis of the operative treatment. Because of the practical clinical and surgical significance of trauma as an etiologic factor I have suggested that diaphragmatic hernia be classified into two main groups, nontraumatic and traumatic. I have subdivided these two groups according to the various types.

Nontraumatic hernia. A nontraumatic diaphragmatic hernia may be congenital or acquired. If it is congenital the hernia is attributable to embryologic deficiency and usually does not have a hernial sac. The common sites of a congenital hernia, in the probable order of frequency of occurrence are (1) through the pleuroperitoneal hiatus, (2) through the gap left by partial absence of the diaphragm, a gap which is usually situated in the posterior portion of the muscle, (3) through the esophageal hiatus due to a deficiency of the circular muscle bundles of the hiatus, (4) through the esophageal hiatus due to deficiency of the esophagus which is not elongated sufficiently to extend to the diaphragm, thus causing varying amounts of stomach to remain above the diaphragm depending on the amount of shortening of the esophagus, and (5) through an anterior subcostosternal opening (foramen of Morgagni or Larrey's spaces).

I have used the term 'pleuroperitoneal hiatus' to designate a congenital complete opening between the pleural and peritoneal cavities due to a lack of complete fusion of the septum transversum and the pleuroperitoneal membrane. Hernias occurring through this open-

ing do not have a hernial sac. When there is incomplete muscular formation of the diaphragm in this region of fusion of the pleuroperitoneal membrane and septum transversum but complete covering of the space with pleural and peritoneal membranes which complete the separation of the abdominal from the pleural cavities, this space of muscular deficiency of the diaphragm is called the foramen of Bochdalek. Hernias occurring through this partially defective region of the completed diaphragm would have a hernial sac of peritoneum and pleura. I have not encountered a diaphragmatic hernia in this region which had a hernial sac.

If the hernia is acquired after birth the sites of occurrence are (1) through the esophageal hiatus, a type in which there is a hernial sac, (2) through the region of fusion of the Anlage of the diaphragm, and (3) at sites named under the congenital types of hernia.

Traumatic hernia. Traumatic diaphragmatic hernia may be caused by direct or indirect injury or by inflammatory necrosis of the diaphragm. In cases of indirect injury of the diaphragm the hernia may occur at any point including points of embryologic fusion but the most common sites are the dome and the posterior half of the left part of the diaphragm. On the other hand the hernia may occur in the right part of the diaphragm. It usually is the result of a severe, crushing injury. When the hernia occurs through the esophageal opening there is a sac but when it occurs through the leaf of the diaphragm there usually is no sac. In case of direct injury of the diaphragm hernia may occur at any point and is usually the result of penetrating wounds, such as those inflicted by a gun or knife.

Rupture of the diaphragm may be the result of inflammatory necrosis, which in turn, has been caused by subdiaphragmatic abscess. Again rupture may follow necrosis caused by drainage tubes which have been introduced into pyemic cavities. In these cases the opening usually is situated in the posterior part of the diaphragm and there is no hernial sac.

CLINICAL AND SURGICAL CONSIDERATIONS

In my experience the most common types of diaphragmatic hernia which require surgical

TABLE L.—DATA IN 430 CASES OF DIAPHRAGMATIC HERNIA IN WHICH OPERATION WAS PERFORMED

Site of opening	Cases	Cause	Contents of hernia	Cases

caused by laceration of a normal diaphragm. However they also may be of congenital origin and may result from congenital structural deficiency of the diaphragm. The symptoms in these cases are more varied and severe than those in the first group because of the multiple structures involved and are often more acute in onset. The initial symptoms may be those of acute intestinal or gastric obstruction or severe hemorrhage.

From the standpoint of treatment diaphragmatic hernia is primarily a mechanical condition and the only treatment which will relieve the condition is operative repair or reconstruction of the abnormal opening in the diaphragm after replacement of the herniated viscera into the abdomen. The indications for surgical intervention and methods and technique of surgical procedures depend on the type, situation and size of the defect in the structure of the diaphragmatic muscle, the kind, number and amount of abdominal viscera involved in the hernia and whether or not the viscera are enclosed in the hernial sac.

In the treatment of all hernias that have occurred through the left portion of the diaphragm I prefer the abdominal approach by means of an oblique left rectus incision starting at the ensiform cartilage and extending to the outer border of the rectus muscle. I believe there is less risk of the occurrence of thor-

acic complications when this approach is used. It is of particular advantage in cases of esophageal hernia for the herniated stomach is usually confined in a sac in the posterior part of the mediastinum and does not enter the true pleural cavity.

In the repair of hernias through the right portion of the diaphragm I prefer the thoracic approach because the large right lobe of the liver makes the abnormal opening in the diaphragm inaccessible from the abdominal approach.

The technical difficulties of adequate exposure of the hernial openings through the left portion of the diaphragm and the esophageal hiatus are often considerable because of fixation of the left lobe of the liver to the leaf of the diaphragm. The exposure of these hernial openings is greatly facilitated by cutting the suspensory ligament and retracting the left lobe of the liver to the right. This can be accomplished when the left lobe is small by folding it on itself and when it is large by retracting it forward into the wound. The spleen is often adherent to the posterior part of the diaphragm and to the margins of hernial openings but usually can be separated from these structures by blunt dissection. In some instances the spleen has been so traumatized by the injury and so bound into an abnormal position by adhesions, that it cannot be sep-

Fig. 2. Situations of congenital structural defects and traumatic lacerations of the diaphragm which cause the more common types of diaphragmatic hernia. (Courtesy *Western Journal of Surgery*.)

erated from the structures at the site of the hernial opening without seriously injuring it. This is likely to occur in the traumatic types of hernia and occasionally in esophageal hiatus hernia. In these cases splenectomy is necessary.

Paralysis of the diaphragm produced by temporary or permanent interruption of the phrenic nerve is of value as a procedure preliminary to radical operative repair of esophageal hiatus hernias. It is a necessary procedure in the surgical treatment of partial thoracic stomach resulting from a congenitally short esophagus. In some cases in which radical operative repair is contraindicated interruption of the phrenic nerve may be used as a palliative measure.

ESOPHAGEAL HIATUS HERNIA

Herniation of the abdominal viscera through the esophageal hiatus may be present at birth or may occur at any time during life. The occurrence at birth of this type of hernia is relatively uncommon as compared with other types of diaphragmatic hernia of essentially congenital origin but esophageal hiatus hernia is the most common type of diaphragmatic hernia which is encountered in adult life. These hernias are of considerable general interest because of the relative frequency of

their occurrence, their indefinite causation, the variation of the relationship between the defective esophageal hiatus and the structures involved in the hernia, the progressive character of their development, the varied and complex symptoms produced by them and because of their treatment which may be conservative if the hernias are small and symptoms mild but which may embrace surgical treatment if the hernias are large.

The symptoms of esophageal hiatus hernia may begin at birth or at any time during later life. Because of the progressive character of this type of hernia, the symptoms vary as the hernia becomes larger depending on the degree and type of herniation present. Therefore because of changing symptoms several different clinical diagnoses can be made in the same case depending on the time at which the patient is examined. Accordingly the condition may be termed the *masquerader* of the upper part of the abdomen. This I believe is the most important clinical consideration of diaphragmatic hernias through the esophageal hiatus. In a study of 343 cases of this type of hernia in which I have performed operations (Table I) it was found that an average of three previous erroneous clinical diagnoses had been made in these cases before the correct diagnosis was established. The common erroneous

diagnoses in order of frequency were found to be cholecystitis, cholelithiasis, gastric ulcer, duodenal ulcer, hyperacidity, secondary anemia, cardiac disease, carcinoma of the cardia, stricture of the esophagus, appendicitis, and intestinal obstruction. In 34 of the 343 cases the patients had been operated on previously for other conditions without complete relief of symptoms. They were completely relieved of symptoms after repair of the hernia.

The chief symptoms of esophageal hiatus hernia are pain, distress, gaseous eructation, vomiting, dyspnea, hemorrhage, weakness, anemia, and palpitation of the heart. At the onset the symptoms are usually mild; they consist of epigastric distress that is projected through to the back and which comes on in the course of or shortly after a heavy meal. However, at times the distress may be brought on by taking anything into an empty stomach, even a cupful of coffee. The attacks of distress are usually similar to one another in character but vary in intensity depending on the amount of stomach that becomes incorporated in the hernia and the degree of interference with the diaphragm as well as the size of the hernial orifice and the associated complications, such as traumatic ulcer and incarceration of the stomach.

As the amount of the stomach incorporated in the hernia increases, the attacks become more severe. The pain is projected straight through to the back and to the lower left side of the thorax, is more marked to the left of the spinal column than elsewhere in the back and often appears between the scapulae. This pain may be agonizing and difficulty is experienced in belching of gas and vomiting because of spasm of the diaphragm and reflex cardio-spasm. The spasm of the diaphragm produces an hourglass deformity of the stomach which interferes with emptying of the upper loculus and causes increased intragastric pressure. The pressure of the herniated portion of the stomach on the lower part of the esophagus also interferes with the belching of gas or vomiting. Spasm of the diaphragm commonly is associated with phrenic pain which is referred to the left shoulder and at times may be projected down the arm. The increased pressure within the thorax causes cardiac embar-

assment with palpitation and tachycardia. The pressure on the lung and the interference with the motion of the diaphragm cause dyspnea. These symptoms are augmented when the patient lies down and in the more severe instances of the condition it is necessary for patients to sit up to breathe. The attacks may last for a few minutes to several hours and occasionally they are considered to be caused by coronary sclerosis or by myocardial disease. The attacks usually are relieved by vomiting and often recur immediately after food is taken.

The intervals between attacks often last for weeks or months. It is probable that during the interval between attacks the stomach is not incorporated in the hernial ring but is situated in its normal position below the diaphragm. When the attacks become more or less constant, the constancy usually indicates that the stomach has become fixed in the thorax by adhesions. All the early symptoms of pressure are augmented during the attacks. Weight is lost because of the patient's inability to retain food and because of the marked restriction in diet. The latter is the result of the patient's fear of bringing on an acute attack. The vomiting is more severe than in early attacks and often is of the retention type. During the severe vomiting the vomitus may contain blood. If the attacks are of long standing the patient not uncommonly has a burning sensation in the epigastrium after meals, which is relieved by taking small quantities of food. If a large amount of food is taken it may bring on one of the attacks that is associated with incarceration of the stomach. Many of these patients present a comparatively typical syndrome of peptic ulcer; are given medical care and obtain partial relief because they take a restricted amount of food at frequent intervals.

Hemorrhage is not an uncommon sign. It is due to a traumatic ulcer which is usually situated in the lower end of the esophagus close to its juncture with the stomach; it may be found near the lesser curvature in that portion of the stomach which is in the hernial sac. These traumatic ulcers result from the to-and-fro action of the stomach in the hernial ring when the hernia is small as well as from the

forceful pressure exerted on the large distorted and congested stomach during the attacks of vomiting when the hernia is large. There is also the additional factor of regurgitation of gastric juices into the lower part of the esophagus which produces esophagitis.

The bleeding from the traumatic erosions may be severe and hematemesis or melena is often one of the chief signs. This type of hemorrhage is more common in cases in which repeated severe attacks of obstruction occur from incarceration of the stomach in the hernial sac than in other cases. In some instances the hemorrhage that results from the ulceration is severe enough to endanger life. Traumatic ulcers which may be multiple are usually relatively superficial and their presence depends on the mechanical derangement of the herniated stomach. After repair of the hernia and replacement of the stomach into its normal position most of these traumatic ulcerations heal spontaneously. In several cases the traumatic ulcer has become more deeply seated, has simulated the usual type of peptic ulcer and has not healed after repair of the hernia. In the few cases of this type that I have seen the symptoms have been of long standing or severe incarceration of the stomach has occurred.

In other instances the patient may not be aware of any bleeding and may have severe secondary anemia resulting from occult hemorrhage into the stool. I should like to emphasize that secondary anemia is one of the important clinical manifestations of this type of hernia.

In cases in which surgical treatment of the hernia is considered one of the most important groups is that in which the symptoms simulate angina pectoris. Often however there are no definite findings on which the diagnosis of coronary disease can be established. It is to be remembered that although a patient has a definite esophageal hiatus hernia that could explain the symptoms, he also can have coronary sclerosis without proved signs and if this latter condition is present, it constitutes a marked hazard to surgical intervention for the hernia.

From the standpoint of general management, cases of esophageal hiatus hernia may

be divided into three groups. In the first group the hernias are small, are recognized roentgenologically often during the course of a general examination and produce few or no symptoms. No treatment is indicated in this group of cases. The second group includes those cases in which the symptoms are only moderately severe and the hernias are of moderate size. In many of the cases in this group conservative treatment such as regulation of diet and reduction of weight is sufficient to relieve the symptoms. The third group includes those cases in which there is no response to conservative measures, the hernias usually are large and in many cases in my experience there are complications, such as incarceration of the stomach or gastric erosion. In this group of cases the only treatment that assures relief of symptoms is operative repair of the hernia.

In all cases in which a third or more of the stomach is involved in the hernia, surgical intervention should be considered because the condition will progress and usually the rate at which the enlargement increases becomes more rapid after the hernia has attained this size. Operation should be performed before severe incarceration with consequent obstruction and traumatic lesions of the stomach has occurred. The operative risk is increased by gastric retention and the technical difficulties are enhanced by fixation of the stomach to the diaphragm and to the hernial sac within the thorax. In all cases in which the colon is involved in the hernia, early operation is necessary because of the danger of occurrence of intestinal obstruction.

While all hernias through the esophageal hiatus are considered under the general term 'esophageal hiatus hernia,' three different types are important from the standpoint of surgical technique. In the first type the esophagus has maintained its attachment to the diaphragm and the cardinal end of the stomach has herniated through the abnormal opening along the side of the esophagus. This is commonly called a para-esophageal hiatus hernia. It is however relatively infrequent and does not constitute more than 20 to 25 per cent of cases in which the patient comes to surgical treatment. In the second type the esophagus is markedly retracted or shortened into the

Fig. 3. (Courtesy *American Journal of Surgery* 3)

mediastinum but is long enough to reach the diaphragm when traction is exerted. From 75 to 80 per cent of cases in which treatment is surgical are of this type. The hernias are usually larger than those of the first type and the results are not as favorable from a surgical standpoint, for recurrences are more likely to develop because of the difficulty of re-establishing fixation of the lower part of the esophagus to the diaphragm. The third type of hernia is that of the true short esophagus with partial thoracic stomach and may also include cases of cicatricial contraction with fixation of the esophagus. This type of hernia presents an entirely different surgical problem from the true esophageal hiatus hernia (Fig. 3).

Interruption of the phrenic nerve. Temporary interruption of the left phrenic nerve is an advisable procedure preliminary to abdominal

repair of most esophageal hiatus hernias. This is particularly true in adults. In infants it is usually not necessary. Temporary interruption of the phrenic nerve is accomplished by crushing the nerve with forceps. Following this procedure the function of the diaphragm is impaired for from 3 to 6 months and at the end of that time normal or nearly normal function will be re-established. In this type of hernia permanent paralysis of the diaphragm is rarely necessary. In fact I prefer not to have the paralysis of the diaphragm complete even after the crushing of the nerve because a slight amount of motion will prevent atrophy of the muscles of the diaphragm. In cases in which re-establishment of function of the diaphragm is not desired because of the danger of recurrence of the hernia paralysis can be made permanent by cutting or evulsing the phrenic

Fig. 4. The more common types of structurally deficient esophageal openings which permit herniation of the stomach into the posterior mediastinum and the method of repair of each type of opening with fascia lata and linen after removal of the hernial sac. (Courtesy *Western Journal of Surgery* 5)

nerve. As a procedure preliminary to radical surgical treatment, interruption of the phrenic nerve is often of value in treatment of incarcerated and strangulated hernias because it prevents spasm of muscle and causes relaxation of the hernial ring.

Permanent interruption of the phrenic nerve may be a necessary procedure in the surgical treatment in a case in which part of the stomach lies in the thorax due to a congenitally short esophagus. However I wish to emphasize that permanent interruption of the phrenic nerve is rarely necessary and should never be done in cases of esophageal hiatus hernia until it is definitely ascertained that it is not advisable to re-establish the function of the diaphragm. It should be emphasized also that this procedure cannot replace the operative repair of the hernia. It is important to bear in mind that the atrophy of the diaphragmatic muscle which follows permanent interruption of the phrenic nerve may make it impossible to obtain a satisfactory result in the event that further repair of the hernia is necessary.

Radical surgical repair. I prefer the abdominal approach in all cases of esophageal hiatus

hernia because the herniated viscera are contained in a sac in the posterior mediastinum and do not enter the true pleural cavity. As stated before an oblique incision is made in the left rectus muscle and peritoneum from the ensiform cartilage to the outer border of the muscle. The technical difficulties of adequate exposure of the esophageal hiatus are often considerable because of fixation of the left lobe of the liver to the leaf of the diaphragm. The exposure of the hiatus is greatly facilitated by cutting the suspensory ligament and retracting the left lobe of the liver to the right. This can be accomplished when the left lobe is small by folding it on itself and when it is large by retracting it forward into the incision. The spleen is often very adherent to the posterior part of the diaphragm near the site of the hernial opening but usually it can be separated from these structures by blunt dissection. It is retracted posteriorly by a specially constructed retractor. In some instances the spleen may be almost drawn into the hiatus and may be so traumatized by separating it from its peritoneal attachments that its removal is advisable.

Fig. 5. Patient, red 49 years. Herniation of the caudal end of the stomach through the esophageal hiatus and some displacement of the lower part of the esophagus (condition previously diagnosed as disease of the gall bladder). a Same patient as in b. anterior margin over the posterior margin of the opening. c, Roentgenogram showing same patient as presented in a and b, 3 weeks after repair of the hernia. The entire stomach is now below the diaphragm which is elevated because of the temporary interruption of the phrenic nerve. The esophagus is in normal position. (Courtesy of the *Annals of Surgery* 4.)

Hernias through the esophageal hiatus are true hernias each has an hernial sac consisting of abdominal peritoneum which is continuous with the serosa of the stomach. The attachment of the sac to the stomach must be separated and the sac must be either completely removed or permitted to retract into the posterior portion of the mediastinum. I believe that this is one of the most important technical considerations in the surgical treatment of this type of hernia.

After the sac has been removed the enlarged defective esophageal hiatus is repaired by overlapping the margins of the opening (Fig. 4). In many instances it is necessary to elevate the repaired hiatus to a higher position on the esophagus. This is an important procedure in those cases in which the esophagus is short or is elevated into the thoracic cavity (Fig. 5). The hiatus is usually repaired to the left of the esophagus but in some cases it is necessary partially to repair it both to the right and to the left of the esophagus (Fig. 6). In some instances the defect of the esophageal hiatus is posterior and it extends to the spinal column. In repair of this type of opening the margins posterior to the esophagus must be overlapped. This condition is often thought to be a herniation through the aortic opening

but over the aorta there usually is an imperfectly developed fibrous band which is the margin of the defective esophageal hiatus (Fig. 7). The closure is usually made with living sutures of fascia lata, which are removed from the thigh. The overlapped margins of the hernial opening are first stabilized with interrupted linen sutures. The fascia lata is then woven into the tissues by continuous suture and fixed in the tissues with interrupted linen sutures.

In many instances in which the stomach is incarcerated or obstructed it is impossible to pass a stomach tube into the obstructed loculus of the stomach before operation. In these cases it is advisable soon after the abdomen is opened, to pass a stomach tube and to direct it into the obstructed portion of the stomach in order to empty the gastric contents before any attempt is made to reduce the herniated viscera, because of the danger of regurgitation and aspiration of gastric contents into the lungs. Before closure of the defective esophageal hiatus is completed around the lower part of the esophagus, it is important that a stomach tube of large caliber be passed through the esophagus into the stomach to aid in the reconstruction of the esophageal opening and to prevent constriction of the

esophagus by a tight closure. The loose areolar tissue or a small portion of the esophageal wall at the cardia is incorporated in the innermost margin of the closure by a suture of chromic catgut.

The abdomen always should be thoroughly explored for the presence of any other lesion particularly of the stomach or gall bladder. In some cases it may be necessary to operate on other associated lesions. However I do not believe it advisable to carry out any additional surgical procedure at the time the hernia is repaired unless it is imperative. It is well to know however whether the patient has gall stones or any other lesion in the upper part of the abdomen which might account for subsequent symptoms.

Inasmuch as the surgical treatment of this type of hernia is a repair of an abnormally large hiatus of the esophagus and not a complete closure of an abnormal opening it is associated with a higher percentage of recurrence than any other type of diaphragmatic hernia. In fact 9 out of 10 recurrences in the entire

series of 430 cases were of this type of hernia. Symptoms of 4 of the 9 patients who had recurrences were severe enough to require a second operation. There were 7 deaths (2.0 per cent) in the 343 cases of diaphragmatic hernia through the esophageal hiatus.

Surgical repair of hernias with congenitally short esophagus. The surgical treatment of congenitally short esophagus with partial thoracic stomach presents an entirely different technical problem from that of other types of esophageal hiatus hernia. The essential consideration in the surgical treatment of esophageal hiatus hernia is that of replacement of the herniated stomach into the abdomen, the removal or obliteration of the hernial sac and the repair and reconstruction of the esophageal hiatus accurately around the lower part of the esophagus.

Congenitally short esophagus with partial thoracic stomach is not a true hernia through the diaphragm in that the stomach has never been in its normal position below the diaphragm because of the short esophagus. The

Fig. 5. Patient, aged 49 years. Herniation of the caudal end of the stomach through the esophageal hiatus and some displacement of the lower part of the esophagus (condition previously diagnosed as disease of the gall bladder). Same patient as in Fig. 1. Large esophageal hiatus repaired: the left of the esophagus with interrupted silk sutures and continuous sutures of fascia lata by laying the

anterior margin over the posterior margin of the opening. c, Roentgenogram showing same patient as presented in a and b, 3 weeks after repair of the hernia. Hernias through the esophageal hiatus are true hernias; each has a hernial sac consisting of abdominal peritoneum which is continuous with the serosa of the stomach. The attachment of the sac to the stomach must be separated and the sac must be either completely removed or permitted to retract into the posterior portion of the mediastinum. I believe that this is one of the most important technical considerations in the surgical treatment of this type of hernia.

After the sac has been removed the enlarged defective esophageal hiatus is repaired by overlapping the margins of the opening (Fig. 4). In many instances it is necessary to elevate the repaired hiatus to a higher position on the esophagus. This is an important procedure in those cases in which the esophagus is short or is elevated into the thoracic cavity (Fig. 5). The hiatus is usually repaired to the left of the esophagus but in some cases it is necessary partially to repair it both to the right and to the left of the esophagus (Fig. 6). In some instances the defect of the esophageal hiatus is posterior and it extends to the spinal column. In repair of this type of opening the margins posterior to the esophagus must be overlapped. This condition is often thought to be a herniation through the aortic opening

but over the aorta there usually is an imperfectly developed fibrous band which is the margin of the defective esophageal hiatus (Fig. 7). The closure is usually made with living sutures of fascia lata which are removed from the thigh. The overlapped margins of the hernial opening are first stabilized with interrupted linen sutures. The fascia lata is then woven into the tissues by continuous suture and fixed in the tissues with interrupted linen sutures.

In many instances in which the stomach is incarcerated or obstructed it is impossible to pass a stomach tube into the obstructed lumen of the stomach before operation. In these cases it is advisable soon after the abdomen is opened to pass a stomach tube and to direct it into the obstructed portion of the stomach in order to empty the gastric contents before any attempt is made to reduce the herniated viscera, because of the danger of regurgitation and aspiration of gastric contents into the lungs. Before closure of the defective esophageal hiatus is completed around the lower part of the esophagus, it is important that a stomach tube of large caliber be passed through the esophagus into the stomach to aid in the reconstruction of the esophageal opening and to prevent constriction of the

The esophagus is in normal position. (Courtesy *Annals of Surgery* 4.)

surgical problem in these cases is that of reconstructing the diaphragm over the elevated portion of the stomach this can be accomplished if the esophagus is not too short. By complete and permanent interruption of the phrenic nerve the diaphragm usually can be elevated from 2 to 5 centimeters and then by complete separation of the attachment of the esophageal hiatus, from 2 to 3 centimeters of the esophagus can be drawn down into the abdomen. The elevation of the diaphragm and the pulling down of as much as possible of the esophagus into the abdomen permit the esophageal hiatus to be closed around the lower end of the esophagus by this means the thoracic portion of the stomach is placed below the diaphragm

the posterior portion of the diaphragm and those through the foramen of Morgagni (Larrey's spaces)

In the first two types there is rarely if ever an hernial sac and the abdominal viscera are in direct contact with the thoracic viscera. In the third type (subcostosternal) there is always an hernial sac which consists of peritoneum and parietal pleura.

The symptoms of congenital types of diaphragmatic hernia due to structural deficiencies in the formation of the diaphragm in which multiple abdominal viscera are involved and which are rarely confined in an hernial sac are often complex. This complexity is due to mechanical interference with the function of the herniated viscera as well as to marked interference with the function of the heart and lungs. Because of the occurrence of the hernia at birth the respiratory and cardiac symptoms are usually the most severe. They are due to the marked unilateral derangement of intrathoracic pressure at a time when the compensatory respiratory and cardiac reserves have not been developed to a sufficient degree to maintain function of these organs. Many infants born with these congenital defects die

CONGENITAL DIAPHRAGMATIC HERNIAS DUE TO MALFORMATION AND STRUCTURAL DEFICIENCIES OF THE DIAPHRAGM

Congenital diaphragmatic hernias may occur through either the right or the left side of the diaphragm but the latter site is much more common. The common hernias of this type are those through the pleuropentoneal hiatus those due to the lack of formation of

Fig. 8 Patient, aged 4 months. a and b. Pleuroperitoneal hiatus hernia with herniation of many loops of large and small bowel in the left side of the thoracic cavity. Marked displacement of the mediastinum and heart to the right. The stomach is dilated and below the diaphragm

c. Same patient on re-examination 1 year after operation. The stomach and the intestines are entirely below the diaphragm, which is of normal contour and position. The heart and the mediastinum are in normal position. Both pulmonary fields normal. (Courtesy *Annals of Surgery* 4.)

in the first few hours or days of life. However if the respiratory and cardiac mechanisms are able to compensate for the presence of the abdominal viscera in the thorax these patients may live on to childhood or even to adult life without any great amount of disability or symptoms provided that intestinal or gastric obstruction does not develop. Obstruction is less likely to develop in these cases than in the cases of traumatic hernia because there are usually fewer adhesions between the abdominal and the thoracic viscera. When the stomach is involved in these congenital hernias it usually becomes dilated and symptoms of partial gastric obstruction are relatively common. Intestinal obstruction may occur owing to bands of adhesions between the omentum and loops of bowel or owing to inflammatory conditions of the bowel. Inasmuch as there is usually a nonrotation of the right portion of the colon and the cecum and the appendix is in the left side of the thorax appendicitis may develop and produce a serious hazard to life.

In the surgical treatment the approach in the first two types may be either thoracic or abdominal but I prefer the abdominal approach and an oblique left rectus incision. In the third type (subcostosternal) the approach should always be through the abdomen and

usually with an oblique right rectus incision or a transverse incision in the epigastrium. I prefer the oblique right rectus incision.

Pleuroperitoneal hiatus hernia. These hernias occur in the posterolateral portion of the diaphragm and are due to failure of fusion of the pleuroperitoneal membrane and the septum transversum. The defect is usually triangular with the apex toward the median portion of the diaphragm. The defect usually extends to the thoracic wall but occasionally an imperfectly developed band of muscle tissue extends along the thoracic wall. These hernias do not have hernial sacs and there is a direct communication between the abdominal and the thoracic cavity.

The most common abdominal viscera involved in this type of hernia are the colon and the small bowel. There may or may not be herniation of the spleen and stomach. There is often a failure of rotation of the colon and the entire right side of the colon (appendix and cecum) the terminal part of the ileum and all of the small intestines to the jejunum are involved in the hernia (Fig. 8).

This type of hernia is said to be the most common of the congenital types of hernia due to structural deficiencies. These hernias are present at birth. Many of the infants suffering

Fig 7 Patient aged 7 years. a, Esophageal hiatus hernia with herniation of the pyloric two-thirds of the stomach into the right thoracic cavity. Stomach is enormously dilated due to incarceration and obstruction (condition previously diagnosed as liver with obstruction). b Same patient as in a. The enlarged hiatus, defective posteriorly, has been repaired with interrupted silk sutures and

continuous sutures of fascia lata by overlapping laterally in front of the aorta. c, Same patient 1 time of diagnosis. The esophagus is in normal position. (Courtesy *Annals of Surgery* 4.)

surgical problem in these cases is that of reconstructing the diaphragm over the elevated portion of the stomach. This can be accomplished if the esophagus is not too short. By complete and permanent interruption of the phrenic nerve the diaphragm usually can be elevated from 2 to 5 centimeters and then by complete separation of the attachment of the esophagus from the attachments around the esophageal hiatus from 2 to 3 centimeters of the esophagus can be drawn down into the abdomen. The elevation of the diaphragm and the pulling down of as much as possible of the esophagus into the abdomen permit the esophageal hiatus to be closed around the lower end of the esophagus by this means the thoracic portion of the stomach is placed below the diaphragm.

CONGENITAL DIAPHRAGMATIC HERNIAS DUE TO MALFORMATION AND STRUCTURAL DEFICIENCIES OF THE DIAPHRAGM

Congenital diaphragmatic hernias may occur through either the right or the left side of the diaphragm but the latter site is much more common. The common hernias of this type are those through the pleuroperitoneal hiatus, those due to the lack of formation of

the posterior portion of the diaphragm and those through the foramen of Morgagni (Larrey's spaces).

In the first two types there is rarely if ever an hernial sac and the abdominal viscera are in direct contact with the thoracic viscera. In the third type (subcostosternal) there is always an hernial sac which consists of peritoneum and parietal pleura.

The symptoms of congenital types of diaphragmatic hernia due to structural deficiencies in the formation of the diaphragm in which multiple abdominal viscera are involved and which are rarely confined in an hernial sac are often complex. This complexity is due to mechanical interference with the function of the herniated viscera as well as to marked interference with the function of the heart and lungs. Because of the occurrence of the hernia at birth the respiratory and cardiac symptoms are usually the most severe. They are due to the marked unilateral derangement of intrathoracic pressure at a time when the compensatory respiratory and cardiac reserves have not been developed to a sufficient degree to maintain function of these organs. Many infants born with these congenital defects die

Fig 10 Same case as in Figure 9. a At operation absence of posterior part of left side of diaphragm repair of defect by suturing posterior margin of diaphragm to intercostal muscles with interrupted silk sutures and with fascia lata. b Same case after operation. pletely closed the air is aspirated from the pleural cavity through a catheter connected to a suction apparatus. At the time of withdrawal of the catheter the last suture is tied and the communication between the thorax and the abdomen is closed.

One of the chief dangers associated with the repair of hernias of this type is the marked alteration of intrathoracic or intra abdominal pressure. It is important that respiratory function be maintained by positive pressure with oxygen during the operation and that at the completion of the operation negative pressure be obtained and secured in the thoracic cavity. A roentgenogram should be taken at the completion of the operation to see that there is no shift of the mediastinum due to the pneumothorax. I do not permit patient to leave the operating table until I have seen the roentgenogram. If any shift occurs, more air is withdrawn to maintain mediastinum in midline.

In my series of 9 cases of hernia through the pleuropentoneal hiatus there were no recurrences and 3 deaths.

Congenital absence of the posterior portion of the diaphragm. This type of hernia is due to

failure of the formation of that portion of the diaphragm which is derived from the pleuropentoneal membrane. The defect is in the posterolateral portion of the diaphragm and usually extends posteriorly from the eighth rib and medially to the esophageal hiatus. Such an hernia usually does not have a sac but there may be an imperfectly developed enveloping membrane of peritoneum and omentum which simulates a sac. These hernias may be considered an enlargement of the foregoing pleuropentoneal type in that the essential difference is a much more extensive congenital defect in the formation of the diaphragm. There are more abdominal viscera involved than in the pleuropentoneal hernia as the stomach and spleen, also the large and small intestine often are included. The left kidney may be elevated above normal level into pleural cavity (Figs. 9 and 10).

The surgical problems associated with hernia of this type are the same as those of pleuropentoneal hernia as far as altered intra abdominal and intrathoracic pressure is concerned but in addition there is the problem of

b

intrathoracic pressure and thoracic visceral relationships surgical intervention should be instituted as soon as possible because of the danger of intestinal obstruction. If nourishment can be maintained, it is well to delay operation for 2 to 3 months after birth in order to permit some development of their necessary respiratory mechanism. If operation is delayed for too long a period, the abdominal viscera will have lost their right of residence in the abdomen. By this I mean that the abdominal cavity will not have developed sufficiently to contain them and there will be marked increase in the intra-abdominal pressure when the viscera are replaced into the abdomen.

In repair of small hernias of this type the opening can be closed without interruption of the phrenic nerve. On the other hand in repair of large hernias interruption of the phrenic nerve is a necessary procedure. Each opening is closed by overlapping the margins for from 2 to 3 centimeters. If the patient is an infant, this closure is made with interrupted silk sutures. Before the opening is com-

from them die in the first few hours or days of life because of respiratory and cardiac embarrassment and before surgical intervention can be instituted. In treating those infants who are able to survive in spite of the abnormal

There is some difference of opinion as to whether this type of hernia should be classified as congenital or acquired hernia. It is impossible to explain its occurrence on a basis of faulty fusion or improper disposition of the embryonic mesodermic elements which go to form the diaphragm, as this anterior portion of the diaphragm is derived from the septum transversum only. But the consistency of the location of the hernial opening, the fairly constant relation of the neck of the hernial sac to the round and falciform ligaments of the liver and the frequency with which the hernial sac protrudes into the right side of the thoracic cavity at the same point of entrance at the cardiophrenic angle, as well as the often associated nonrotation of the right portion of the colon, all strongly suggest a fundamental embryologic basis. These hernias are essentially direct hernias through a congenital defect in the structure of the diaphragm or faulty attachment of the diaphragm to the sternum and costal cartilages. The constant presence of a peritoneal sac shows that the peritoneum had closed off the abdominal cavity from the pleural cavity before the actual herniation of the abdominal viscera occurred.

Subcostosternal diaphragmatic hernia is one of the two types of diaphragmatic hernia in

my experience which have an hernial sac. The other type is that through the esophageal hiatus. It is interesting that subcostosternal hernia is probably the rarest type of diaphragmatic hernia and esophageal hiatus diaphragmatic hernia is the most common, both are essentially congenital in origin but are rarely present at birth and occur in most instances in later life because of increased abdominal pressure on a congenitally defective diaphragm.

closing this large gap in the diaphragmatic muscle and of reconstructing the attachment of the diaphragmatic muscle to the thoracic wall. In some instances the posterior peritoneal fascia may be utilized in this closure and fixa-

tion to the thoracic wall. If the gap is not too great the closure can be accomplished by complete permanent interruption of the phrenic nerve. If the defect is too large to permit the relaxed diaphragm to span the gap it is necessary to shorten the diameter to the diaphragm by extrapleural resection of ribs.

In 12 cases in my series (Table 1) the hernias were due to congenital absence of a portion of the diaphragm. There were one recurrence and two deaths.

Subcostal hernia through the foramen of Morgagni (Larrey's spaces). Herniation of abdominal viscera through regions of deficiency of muscle in the anterior portion of the diaphragm close to the sternum has received various names such as diaphragmatic hernia through the foramen of Morgagni or through Larrey's fissures or spaces and also substernal retrosternal parasternal or anterior diaphragmatic hernia.

Inasmuch as hernias of this type may occur anteriorly on either side of the midline if an anatomic term is to be used it would be preferable to designate them as subcostosternal diaphragmatic hernias.

cur if there are no subjective symptoms to suggest that an abdominal condition may be present and even though the gastrointestinal tract is examined roentgenologically, no lesion is demonstrated as no abdominal hollow viscus is involved in the hernia. One of the most important clinical considerations in this type of hernia is the possibility of this erroneous diagnosis.

The treatment of subcostosternal hernia is surgical closure of the abnormal opening in the diaphragm after replacement of the abdominal viscera into the abdomen. I prefer an abdominal approach through the upper part of the right rectus muscle because the opening in the diaphragm is accessible and the abdominal contents of the hernia are more safely and easily reduced from the abdominal than from the thoracic side of the diaphragm as the true relationship of the herniated viscera to the hernial sac can be determined accurately.

The method of closure of the neck of the sac and of the defect in the structure of the muscle of the diaphragm depends on the size and character of the opening. Small linear openings may be closed by overlapping the margins. Larger transverse openings extending beneath the sternum are best closed by suturing the anterior margin of the defect in the diaphragmatic muscle to the posterior sheath of the rectus muscle and to the anterior wall of the thorax.

The most satisfactory material for closure of the opening is living suture of fascia lata removed from the thigh and stabilized in the tissues with silk. The round ligament of the liver can be incorporated in this closure to strengthen it as well as to re-establish its position on the anterior wall of the abdomen.

The closure of the large openings is facilitated by paralyzing the right side of the diaphragm by temporary interruption of the right phrenic nerve. This procedure however is not necessary in the closure of small openings. The phrenic nerve can be interrupted in the supraclavicular region after the opening has been explored and it has been determined whether interruption is necessary.

In my series of 430 cases of diaphragmatic hernia, 8 were of the subcostosternal type.

There were no deaths or recurrences following operative treatment.

TRAUMATIC DIAPHRAGMATIC HERNIA

Traumatic diaphragmatic hernia may be caused by direct or indirect injury or by inflammatory necrosis of the diaphragm. In case of indirect injury of the diaphragm, the hernia may occur at any point, including points of embryologic fusion but the most common sites are the dome and the posterior half of the left part of the diaphragm. On the other hand the hernia may occur in the right part of the diaphragm. It usually is the result of a severe, crushing injury. When the hernia occurs through the esophageal opening there is a sac but when it occurs through the leaf of the diaphragm, there usually is no sac. In case of direct injury to the diaphragm the hernia may occur at any point and is usually the result of penetrating wounds such as those inflicted by a gun or knife.

Rupture of the diaphragm may be the result of inflammatory necrosis, which in turn has been caused by subdiaphragmatic abscess. Again, rupture may follow necrosis caused by drainage tubes which have been introduced into empyemate cavities. In these cases the opening usually is situated in the posterior part of the diaphragm and there is no hernial sac.

Traumatic diaphragmatic hernias usually do not present the difficult diagnostic problems which are associated with the esophageal hiatus type of hernia for the occurrence of the injury leads the physician to suspect the possibility of a hernia, except in cases of inflammatory necrosis. The symptoms associated with the traumatic type of hernia progress rapidly are severe, and are attributable to the mechanical interference with the function of the herniated viscera as well as to marked interference with function of the heart and lungs. This mechanical interference is due to the fact that there is no hernial sac and the abdominal viscera are in direct contact with the thoracic viscera. The most marked immediate symptoms are usually those of respiratory and circulatory embarrassment. Traumatic hernias are more frequent in adult life, and the compensatory

The abdominal viscera usually involved in the hernia are the colon omentum ileocecal coil and rarely the stomach.

The symptoms associated with these hernias are often indefinite and depend on the type and amount of abdominal viscera involved in the hernia. They are usually due to impairment of respiration and intestinal obstruction. Among them are dyspnea, cough, and attacks of partial intestinal obstruction and thoracic and abdominal pain.

In the cases in which hollow viscera are involved in the hernia, symptoms occur which suggest the possibility of an hernia or at least the necessity of a roentgenologic examination of the intestinal tract which will determine whether an hernia is present. The cases in

which omentum only is involved in the hernia present a much more difficult diagnostic problem. The symptoms in this type of case are entirely referable to the thorax as a result of the mechanical interference with respiration and expansion of the lungs. These symptoms suggest a primary pulmonary lesion and direct the clinical investigation to roentgenologic study of the thorax. The roentgenologic findings of an increased density in the pulmonary field justify the clinical diagnosis of a primary intrathoracic lesion which may be thought to be an intrathoracic tumor (Fig. 11). This erroneous diagnosis is particularly likely to oc-

In all traumatic hernias through the left side of the diaphragm, I prefer the abdominal approach through an oblique left rectus incision. The herniated viscera are usually adherent to both the abdominal and the thoracic side of the diaphragm and to the structures within the thorax. The adhesions to the margins of the opening and to the under surface of the diaphragm are often extensive and should be separated first. The adhesions to the structures within the thoracic cavity are separated from below upward by approaching them through the hernial opening. The abdominal approach permits this separation of adhesions with little danger of injury to the abdominal or thoracic viscera, because the definite relationship of the herniated structures can be established.

When considerable structure has been lost or the muscle has been torn from its attachment to the thoracic wall the defect in the diaphragm should be repaired by fascia lata stabilized with linen sutures. I believe this to be the most satisfactory type of closure in all these cases. In cases in which the laceration is confined to the dome of the diaphragmatic muscle it usually is advisable to repair the opening by lapping the anterior over the posterior margin. When possible it is advisable to overlap the margins of the opening for from 2 to 3 centimeters. In those cases in which the muscle of the esophageal ring is split great care should be taken in repairing the esophageal hiatus. In cases in which the laceration extends to the margin of the thorax and in which the attachments of the diaphragm are torn from the thoracic wall repair is made by overlapping the lacerated edges of

the leaf of the diaphragm and by resuturing the diaphragmatic muscle to the thoracic wall. This can be accomplished by suturing the diaphragmatic muscle to the intercostal muscles. When possible the diaphragmatic muscle should span two interspaces fixed to the intercostal muscles with fascia lata and made stable with interrupted linen sutures.

In a few instances the relaxation of the diaphragmatic muscle caused by interruption of the phrenic nerve will not be sufficient to permit repair of the defect. In these cases the diameter of the thorax must be narrowed by resecting the lower ribs. It is usually not necessary to resect more than a few inches of the eighth, ninth, and tenth ribs at the angles.

Before the abdomen is closed the herniated viscera should be thoroughly explored to be certain that there has been no injury to a viscus and that there are no bands of adhesions which will interfere with their function. In cases in which there has been considerable obstruction of the large bowel it may be necessary to perform appendicectomy or colostomy at the time of operation.

In my series of 58 cases of traumatic diaphragmatic hernia there were no recurrences and 5 deaths.

RESULTS

In Table II the surgical procedures and operative results in the entire series of 430 cases are given.

cardiac and respiratory reserve usually carries the patient over the acute symptoms if the other associated injuries have not been too great. Later severe hemorrhage from the gastrointestinal tract may occur as a result of incarceration or strangulation of the hollow viscera. If the patient survives the acute condition the later symptoms depend on the viscera involved. The symptoms and signs may consist of obstinate constipation, large quantities of gas in the colon, and attacks of partial or complete intestinal or gastric obstruction. The sudden onset of symptoms in cases of hernia caused by direct or indirect trauma usually is related directly to the injury and there is rarely a question as to the clinical diagnosis. Surgical treatment is demanded because of the

danger of cardiac and respiratory failure or because of intestinal strangulation.

In those types of diaphragmatic hernia which result from inflammatory necrosis of the diaphragmatic muscle the symptoms of hernia are often somewhat obscured by those due to the primary illness. In many instances their true cause is not recognized for a long period because the possibility of a hernia is not considered. In some cases the hernia does not occur for many months after the patient recovers from the primary illness.

Hernias due to direct trauma demand immediate surgical treatment if there is any indication of an associated injury to the hollow viscera. In cases in which the hernia is caused by indirect injury there is less likelihood of a rupture of a hollow viscera and operative interference may be delayed until the acute symptoms caused by the primary injury have subsided; however operation in these cases should be done as soon as possible because of the danger of the occurrence of intestinal obstruction. It is important that the delay should not be long because the herniated abdominal viscera will lose their right of residence in the abdomen. When the protrusion of abdominal viscera into the thoracic cavity is of large size and has lasted for a long time, the herniated viscera become dilated because of mechanical interference to their normal functions and the abdominal cavity which has not contained them for a long time becomes smaller. These factors tend to increase the hazard of operation as well as the risk of recurrence of the hernia, because when these viscera are replaced into the abdomen they markedly increase the intra abdominal pressure.

The surgical approach in traumatic hernias may be through the thorax or through the abdomen. For all hernias through the right side of the diaphragm I prefer the thoracic approach because the large right lobe of the liver interferes with exposure of the right side of the diaphragm if the abdominal approach is used. In hernias of this side the right lobe of the liver is often incorporated in the hernia and its reduction is accomplished more safely when the thoracic approach is used (Figs. 12 and 13).

Beginning nearly a decade ago, attempts were made in the laboratory to develop methods of working on the thoracic aorta with a reasonable degree of safety. Using medium or large sized dogs it was found possible to resect one or two centimeters of aorta and to anastomose the remaining ends for re-establishment of the aortic pathway. Numerous methods of vessel suture were tried and all were discarded in favor of that which employs a continuous mattress stitch of fine silk the suture traversing all layers of the vessel wall and bringing the vessel ends together so that intima comes to intima and the arterial ends are everted. In spite of the large size of the vessel, the great tension on the suture line (because of the aortic elasticity) and the high blood pressure which must be carried by the structure, healing and solid union at the suture line could be expected. On theoretical grounds it would seem preferable to anastomose aortic ends by careful layer to layer approximation (intima abutting to intima, media to media etc.) but our experiments showed this to be followed occasionally by disruption or poor healing. (This method was subsequently employed by Crafoord for use in human subjects but I am firmly convinced that it is less reliable than the everting type of repair.)

From the laboratory certain lessons have been learned which, when augmented by other knowledge can be translated into a practical procedure for removal of aortic constrictions from humans. Exposure through the back must be adequate it is apt to be difficult and bloody because of the great collateral circulation which is encountered in the chest wall. A segment of aorta, 8 to 10 centimeters long must be mobilized from its bed with extreme delicacy and care. To avoid serious hemorrhage the large, thin intercostal arteries must be handled gently

particularly at their junctions with the aorta which are points of extreme weakness and vulnerability. Most coarctations involve only a short segment of vessel and there is sufficient elasticity in the remaining portions of the aorta to allow excision of the constricted part and anastomosis of the remaining ends.

Throughout the operation and in spite of liberal use of hemostats and sutures, there may be considerable blood loss from the transected muscles, rib beds etc. An occasional check on the total loss by measuring the fluid in the suction apparatus and by weighing of discarded sponges provides a satisfactory guide for blood infusions. In this way shock is not treated it is prevented. During closure of the chest, complete re-expansion of the left lung will insure returning the patient to a normal physiological state as quickly as possible. During the first week or two after operation there is usually sufficient collection of fluid in the left pleural cavity to require tapping. It is not necessary to give these patients anticoagulents during the postoperative period, the performance of an extremely accurate anastomosis is the best way of avoiding thrombus formation at the suture line.

In a series of forty personally treated patients with coarctation ranging in age from 7 to 31 years the following results were obtained. The thoracic duct was not injured in any case. In five instances only exploration was carried out the operation was terminated because the narrowed segment of aorta was very long, or else the vessels were surrounded by an inflammatory reaction as a result of previous infection. In thirty five cases the narrowed portion of aorta was excised and the remaining ends of the vessel were brought together. There were five deaths in this group some of which

SURGICAL TREATMENT FOR COARCTATION OF THE AORTA

CONGENITAL obstruction of the thoracic aorta may so impede the peripheral flow of blood that the left ventricle is overworked and may fail in early infancy. Cardiac failure in the newborn period is particularly apt to occur if the heart itself possesses severe malformations. If a human with coarctation of the aorta lives beyond infancy there lies beyond this an uncertain future. In an effort to determine the prognosis for patients with coarctation of the aorta pertinent data have been obtained by my colleagues who made an extensive search of autopsy records in the regional hospitals, including in the study all subjects who were found to have a coarctation at postmortem examination, whether or not the anomaly had contributed to the death. All cases were discarded in which there was a fatality within the first two years of life hoping thereby to exclude the more compli-

cated forms of cardiovascular abnormalities. For those subjects who lived for more than two years, certain generalities can be stated regarding the prognosis. The abnormality was much more common in men than in women. The patients could be placed into four groups of about equal size. In the first quarter were those who had lived a long life—some to well advanced years—and who had had little or no important complaints related to the vascular obstruction. In the second quarter were those who had died suddenly from aortic rupture. This fatal complication was most common in the third decade of life. In the third quarter were those who had died from superimposed *Streptococcus viridans* infection a complication which was most common during the second and third decades. Such infection is of course much less of a threat in the present day of chemotherapy. In the fourth quarter were those who had died of the hypertensive state—from cardiac failure or from intracranial hemorrhage. While intracranial hemorrhage was sometimes encountered in childhood deaths from cardiac failure or intracranial bleeding were most common in the fourth decade. The serious nature of coarctation can be indicated by studying the death rates in humans between the ages of 15 and 30 years. In the general population fatalities in this age range are uncommon in contrast, about forty per cent of patients with coarctation die within this same period of life. Certainly coarctation of the aorta is attended by crippling or fatal sequelae in a high proportion of cases and thus demands the surgeon's attention in devising methods for averting these catastrophes.

ing that occurs through the interventricular septal defect where the flow is from right to left and venous blood from the right ventricle passes out into the overriding aorta directly into the systemic circulation

Arterial oxygen saturation is a direct function of the total mixed venous blood which passes through the lung. A decrease in pulmonary capillary flow existing with intracardiac shunts contributes to arterial oxygen saturation only by reducing the effective pulmonary blood flow. A large right to left shunt will cause anoxemia for the same reason. However as Bing and his associates have pointed out, in uncomplicated pulmonic stenosis where there is simply reduction in pulmonary flow arterial oxygen unsaturation is not produced since in such a case all the mixed venous blood reaches the alveolar capillaries.

Congenital abnormalities of the heart have assumed a particular importance in medical and surgical practice since Blalock and Taussig's significant contribution in May 1945. Taussig emphasizes certain characteristic clinical findings that are helpful in establishing the diagnosis of the tetralogy of Fallot: to wit, the heart is normal in size and usually a basal systolic murmur and pure second sound are audible. The electrocardiogram shows a right axis deviation. The x ray demonstrates an absence of the normal fullness of the pulmonary conus and the lung fields are clear. Fluoroscopy shows no pulsations at the hilus of the lungs.

This same seasoned observer (Taussig) admits there are many variables in the clinical findings. The systolic murmur may be quite loud or entirely absent! The second sound may be diminished or accentuated; it is never reduplicated. Cyanosis may be marked or slight, depending upon the degree of the oxygen unsaturation and the height of the red blood count. The exercise tolerance of the in-

dividual shows a corresponding variation; some persons can walk a mile, some not at all.

Two additional methods of examination have been developed to render more exact the diagnosis of congenital cardiac defects. The Robb-Steinberg technique of angiocardiology provides excellent visualization of the chambers of the heart and great vessels. Particularly is this the case in children of the younger age group. Overriding of the aorta, small or large pulmonary arteries, marked cross chamber filling and right or left sided aortic arches can all be demonstrated by this type of examination. Retrograde injection of diodrast solution through the left common carotid artery can be used as a visual method to demonstrate patent ductus arteriosus and coarctation of the aorta.

Venous catheterization of the heart is the other important method that is helpful in the diagnosis of congenital heart malformations. Blood samples can be obtained via the catheter and the oxygen content of these samples determined. In addition pressure measurements can be accurately determined by the same route. The catheter is manipulated under fluoroscopic guidance and the presence of a septal defect can often be visually determined by actually passing the catheter through the defect. Cournand and Ranges were the first in this country to demonstrate the value of venous catheterization of the heart. Cournand has reported 1,200 such examinations with no fatalities or serious complications. Bing and his associates and Sossman and Dexter and others have contributed valuable information in their publications on physiological studies in congenital heart disease.

Anastomosis of one of the major systemic arteries to the right or left pulmonary artery is often spoken of as the Blalock operation. Blalock and Taussig have advocated this oper-

can be regarded as avoidable in the light of surgical experience which has been obtained subsequently. Specimens removed from the thirty five patients showed a complete block in five and in the remainder there was a tiny opening only one to three millimeters in diameter. In patients surviving removal of a coarctation follow up studies show that there has been no relief of hypertension in one (in whom the anastomosis was known to be poor) whereas, in all other cases there has been an extremely gratifying fall in the arm pressures to normal levels. Concurrent with lowering of arterial pressure in the arms there has been an increase in pulsations in the legs and lower part of the body and a rise in arterial pressures of the legs. In the early part of our work there were apprehensions about the possibilities of a renal ischemia factor the existence of which would prevent a fall in general arterial pressure throughout the body even though an aortic obstruction could be removed surgically. Such fears can now be dispelled because ample evidence has accumulated to show that surgical restitution of a normal aortic pathway will be followed promptly by normal pressure relationships throughout the body.

In these operations certain age restrictions as yet not clearly defined must be necessary because of technical considerations. Below six or seven years the aorta is probably too small to work upon with facility and satisfaction. Above twenty five or thirty years the vessel is apt to be sclerotic above the obstruction or else thinned out below the constriction. If such vessel changes are marked they will militate against surgical excision of a coarctation or will greatly increase the risks of such an undertaking. The optimum ages for procedures of this sort appear to lie between ten and twenty years. This fact points to the great desirability of recognizing

the malformation in young subjects, particularly when it is the cause of hypertension, because in the second decade of life will the surgeon have the best chance of restoring the aortic channel to normal.

These operations are time-consuming and difficult for the anesthetist, the surgeon and the entire team yet a meticulous dissection and technique must be constantly employed. Any careless movement of hand or instrument may cause serious damage to the aorta or one of its tributaries or indeed result in uncontrollable hemorrhage and sudden death. For those who would engage in this type of surgery it is not only necessary to have an intense interest in vascular as well as thoracic surgery but in addition it is essential to practice the maneuvers thoroughly on human cadavers and on living animals before undertaking the reparative procedures on human patients. The aorta has long been regarded as sacrosanct and beyond the surgeon's knife but it is now clear that a knowledge of aortic pathology and a development of special techniques make it possible to correct the most common malformation of this great vessel.

ROBERT E. GROSS

CONGENITAL PULMONARY STENOSIS

THE most frequently encountered type of congenital cardiovascular defect accompanied by cyanosis is termed the tetralogy of Fallot. The four features that constitute the tetralogy of Fallot are pulmonary stenosis or atresia, dextroposition or overriding of the aorta, an interventricular septal defect and right ventricular hypertrophy. This malformation results in a greatly diminished flow of blood through the pulmonary artery. Cyanosis and clubbing of the fingers are due to the venous-arterial mix

sulfonamides and the antibiotics. Third we must consider what damage these agents may do either to the local tissues or the body as a whole. Let us first review the fundamental differences between medical and surgical infections. With medical infections there is a diffuse cellulitis of the organ involved but there is no local destruction of tissue. With surgical infections the disease is usually local and there has been a local breakdown of tissue or a local collection of exudate. It is obvious that medical infections can seldom be treated locally but are best served by some medication which can permeate the tissues of the body and may then be expected to reach the areas of infection through patent and generally dilated blood vessels. In surgical infections, an opportunity is given for local as well as systemic treatment. Medication can often reach infected areas by local treatment when it cannot reach these areas by systemic treatment because of thrombosis of the blood vessels in the periphery of the local lesion. It goes without saying that an infection can be most quickly controlled by bringing the antibacterial agent into contact with the infecting organisms as quickly as possible in the highest concentration that can be tolerated by the tissues of the host. It would seem obvious that in the treatment of surgical infections this can best be accomplished by smaller quantities of the medicine applied locally than those which are required for systemic administration since so much of the latter is lost by its rapid elimination and its uptake by the tissues of the body which are not affected. The local effectiveness of the sulfonamides and the antibiotics or any other antibacterial agent is limited (1) by its solubility in body fluids, (2) by its diffusibility from the vehicle in which it is applied (3) by its inhibition by dead tissue, pus, blood or any other product of tissue disintegration (4) by the inactivating action

of bacterial contaminants and (5) by the resistance of the causative organisms.

It is true that the sulfonamides in general with the possible exception of sulfamylon are inhibited by necrotic tissue and by organic acids which are present in exudates. Furthermore they are relatively insoluble so that they may act as foreign bodies and be mechanically irritating. This is particularly true of sulfon-thiazole and sulfadiazine. On the other hand penicillin, streptomycin and bacitracin are not inhibited by necrotic tissue, pus, or blood are highly soluble and diffusible and if they are introduced in a watery solution or in a water soluble vehicle like carbowax they are available for their antibacterial action and are absorbed through the wall of the local lesion. They are limited only by the resistance of the causative organisms or by the ability of contaminating organisms to produce inactivating ferments. Penicillin seems to be entirely without toxicity even in large doses except for rare cases of idiosyncrasy, but the dermatologists are finding that many individuals develop a sensitivity to it after prolonged application in ointment form. Penicillin's chief limitation is its destruction by penicillinase which is produced mainly by organisms of the coliform group namely *Escherichia coli*, *Pseudomonas pyocyanea*, the aerobacters occasionally by proteus, by certain strains of the *Bacillus subtilis* and by primarily resistant staphylococci.

Streptomycin is not inhibited by these organisms but has a limited spectrum of antibacterial activity. Its chief value is its effectiveness against many gram negative rods as well as certain gram positive cocci and the acid fast bacilli. Its chief limitation is the rapid development of resistance (sometimes within 24 or 48 hours) by organisms which are not killed primarily by high concentrations of the drug. Toxic manifestations limit the dosage and duration of treatment of the strep-

ation to increase the pulmonary blood flow in that there is a definite lack of circulation to the lungs in congenital pulmonary stenosis. The great value of this operation has been demonstrated in several hundred cases that have been managed by Blalock and his associates. In addition to increased pulmonary blood flow Blalock's shunt operation has demonstrated that one of the branches of the aortic arch can usually be connected to a pulmonary artery without encountering insuperable difficulty that cyanotic children withstand anesthetization and temporary occlusion of one pulmonary artery and that the subclavian artery can be divided within the thorax and the collateral circulation to the affected extremity remains adequate.

Blalock prefers an end-to-side union of the subclavian artery to one of the pulmonary arteries. The subclavian branch of the innominate artery is the vessel of choice in that this vessel makes a less acute angle with its parent artery after the anastomosis is performed. The thoracic incision is made on the side opposite to that on which the aorta descends. The aorta descends on the right rather than the left in approximately twenty per cent of the cases of the tetralogy of Fallot. The innominate artery arises on the side opposite to that on which the aorta descends.

Potts and his group have employed lateral anastomosis between the left pulmonary artery and the thoracic aorta. The size of the shunt can be accurately measured by this method and in addition a union between the aorta and the pulmonary artery may be technically simpler in patients past twenty years of age. When a patient has attained most of his growth the gap to be bridged is greater in proportion to the length of the artery.

Holman uses the subclavian artery that arises as a single trunk from the arch of the aorta. If kinking occurs at the origin of the

subclavian artery Holman then divides the pulmonary artery on the heart side of the anastomosis and corrects the kinking by this maneuver. Holman's method may prove a valuable refinement in that it is associated with the least technical difficulties of the three methods of vascular union.

The results of the shunt operation in congenital pulmonary stenosis are immediate improvement in the patient's color, prompt rise in the oxygen saturation of the arterial blood and gradual fall in the red blood count, hemoglobin and hematocrit. It is not possible to say how much the patient's life span is increased but as Taussig says, certainly the patient's enjoyment of life is greatly increased. Perhaps the worth of Blalock's and Taussig's contribution in the management of congenital pulmonary stenosis is best expressed by this note from the mother of a cyanotic child upon whom the Blalock procedure had been performed. "There are no words to express our feelings of gratitude and happiness for making it possible for our little boy to be well and happy and able to play as other children."

H BRODIE STEPHENS

THE TOPICAL USE OF ANTIBIOTICS IN ESTABLISHED SURGICAL INFECTIONS

DURING recent years there has developed a conflict of opinion with regard to the local use of antibiotics in the treatment of infections. I believe that it is possible to resolve this conflict and arrive at a consensus if we can properly classify those cases which can best be treated by systemic administration, by local administration or by a combination of these two.

We must consider first the nature of the infections which surgeons have to treat and second what can be accomplished by the

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

IN the publication *The Practical Nurse*¹ one finds authoritative information on this widely discussed subject. The findings presented as a result of the writer's investigations and the use of material found in studies conducted by national groups give one a comprehensive picture of the situation. In the preface Miss Deming states that this book attempts to show that a new and desirable kind of practical nurse can be developed who will be a partner of the registered nurse—and a welcome one—in giving care to the sick at home and in all types of hospitals.

It is pointed out that something must be done to provide more adequate care for patients in hospitals and homes, for the mentally ill, the chronically ill and the aged. That there may be no misunderstanding regarding the term "practical nurse" the following definition is found in chapter II. The name practical nurse refers to a person with specified training of nine to eighteen months licensed in the state in which he or she is practicing if a state law exists and serving in homes, hospitals, public health or industrial agencies under the direction of a licensed physician and—desirably—the supervision of a professional registered nurse. It is explained that the duties and responsibilities of the licensed practical nurse vary greatly; however a person qualified to meet licensure requirements recognizes the protection which is inherent in a limitation of her duties.

In hospitals and other institutions, the practical nurse has the benefit of supervision of the professional nurse, while in public health and other agencies supervision may be more limited. The guidance and supervision should be such that the practical nurse has a feeling of sharing in the responsibilities. Those employed in the homes work largely under the direction of a physician who can not be expected to follow the details of nursing care, and in this field more than any other there is the need for the licensed practical nurse.

The author emphasizes the need for uniformity of educational standards in schools of practical nursing and the importance of having a well correlated program of theory and practice. Only when and where adequate facilities are available should efforts be made to establish schools of practical nursing which meet accreditation requirements. Then the next step is to make provisions for licensure, and we are warned not to travel ahead of the public's understanding of this new phase in the development of practical nursing care. A well publicized campaign

for licensing the trained practical nurse and vigorous efforts to make clear the difference between the two types of nurses should precede the production of thousands more non-professional nurses. At present, it is not quantity so much as controlled quantity that we need in the field of practical nursing. It is recognized that an intensive educational program must first be carried on in the professional nurse and practical nurse groups. The author pleads for vision which sees through all the veils of habit and tradition by which we are walled in to the real need of the human beings in our communities and the courage to follow that vision and meet those needs.

The list of references accompanying each chapter is especially valuable and should be used by the reader who is uninformed. We have needed such a book for a long time. Because of Miss Deming's varied experiences she is able to present a broad viewpoint and *The Practical Nurse* should be widely read by the professional registered nurse, the practical nurse, the physician and the hospital administrator.

MARY I. BOGARDUS

THE monograph *Hodgkin's Disease and Allied Disorders*² contains chapters on Hodgkin's disease, reticulum cell sarcoma, lymphocytoma and lymphoblastoma, lymphosarcoma, giant follicle lymphoma, histiocytoma and endothelioma. The pathological, clinical and therapeutic aspects of these diseases are thoroughly dealt with; the rich material supplied by the Boston City Hospital, the Collis P. Huntington Memorial Hospital and the Pondville Hospital, being used as bases for discussion. X-ray therapy is discussed briefly without giving dosages because the authors believe that the details of treatment are best carried out by the radiologist. Excellent photomicrographs of the pathologic lesions, and photographs of patients and roentgenograms illustrate the text. A recent photomicrograph of a lymph node from one of the original cases studied by Hodgkin at Guy's Hospital in 1888 is used as an appropriate frontispiece.

Doctors Jackson and Parker have put a wealth of statistical data into their book and for this reason alone it will be consulted as a helpful reference work for a long time. Like all books which describe diseases of unknown etiology it expresses many viewpoints about which there will naturally be dif-

tomyacin which is presently available for systemic use

Bacitracin is not inhibited by any organisms which produce penicillinase. There has been no evidence of local irritation or general toxicity from the local application of bacitracin in over 186 cases of surgical infections. Organisms build up resistance to it slowly in about the same degree as they do to penicillin. It has an antibacterial spectrum similar to penicillin but there are many organisms which are susceptible to it and which are resistant to penicillin. With the relatively impure bacitracin now available there are certain toxic symptoms which limit the dosage but it is believed and expected that these will be eliminated when purification has been completed.

It is not unnatural that those who had war experience failed to see any convincing proof or benefit from local application of either the sulfonamides or penicillin because of the nature of the infections which they had to treat. War wounds are characterized by extensive destruction of tissue which inactivates the sulfonamides and extensive contamination with soil organisms which almost invariably include many gram negative rods that are able to produce penicillinase and thus break down penicillin. These are often pathogenic locally in a wound without invading the body and they may interfere with the local effectiveness of penicillin without interfering with the benefit which may be derived from systemic administration against other more invasive organisms that may be present in the wound.

The last point which I wish to stress is the necessity for determining at the earliest possi-

ble time the organisms which are present in any surgical infection which one has to treat. More than half of them will be found to be due to a mixture of organisms. These must be tested for susceptibility to the agent which one desires to use and for the ability of any of the organisms to inactivate this agent. It is obvious that the patient will receive the best treatment if the surgeon, with the aid of the bacteriology laboratory obtains this information as soon as possible and treats the infection with the agent or a combination of agents best suited to meet the situation. If the lesion is local without any evidence of general spread, it can be treated best by local application only. If there is evidence of a spread of the infection into the surrounding tissue or into the body as a whole systemic administration must also be used.

I am not unmindful of the necessity at all times of maintaining the body as a whole at the highest possible physiological level in order to combat infections nor of the frequent necessity for removing dead tissue, particularly necrotic bone or slough before or at the same time as the local application is made of the appropriate antibacterial agent or combination of antibacterial agents.

Antibiotics may be applied locally either in solution in concentrations of 250 to 1000 units per cubic centimeter or in water soluble ointments in concentrations of 250 to 1000 units per gram of ointment. Usually a treatment once or twice a day is adequate and such treatments can often be carried out in the doctor's office upon an ambulatory patient.

HODGKIN'S DISEASE AND ALLIED DISORDERS. By Henry Jackson, J. A.B., M.D. and Frederic Parker, J. A.B., M.D. New York, Oxford University Press, 1947.

¹THE PRACTICAL NURSE. By Dorothy Deming, R.N. New York: The Commonwealth Fund, 1947.

ferences of opinion. Nevertheless the questions raised by these differences of opinion are ones which may be properly asked for they may well stimulate others to discover the answer.

Most of the book is devoted to a consideration of Hodgkin's disease of which a very full account is given. Of considerable interest is the author's division of Hodgkin's disease into three groups: (1) Hodgkin's paraneoplasia, (2) Hodgkin's granuloma and (3) Hodgkin's sarcoma. They describe differences in the clinical symptoms in the pathologic lesions, and in the prognosis of these three forms of Hodgkin's disease which if verified by other workers, will prove a useful contribution to our knowledge of the disease. However one wonders why the authors have not separated Hodgkin's sarcoma entirely from this group since according to their criteria it appears to be a separate disease unrelated to the others.

The morphology of the characteristic giant cell of Hodgkin's disease is somewhat vaguely described and is not clearly distinguished from some of the other types of giant cells which may be found in the lesions. The criteria for attributing the primary site of the disease to various organs are not plainly set forth in the text nor the legends of the statistical tables.

The discussions of reticulum cell sarcoma, lymphocytoma and lymphoblastoma and lymphosarcoma are of interest, but one wishes that the author's classification and findings had been compared with those of Robb-Smith, Callendar and other workers. It would be helpful to know the counterparts in these other classifications of the lesions described in this book. There is a good description of primary reticulum cell sarcoma of bone.

This book should certainly be read by everyone who has to diagnose and treat patients suffering from these diseases, for while one may differ with some of the opinions expressed by the authors, nevertheless it is a mine of valuable information.

WILLIAM B. WARTMAN.

A NEW approach to the recognition of illness is presented in the reference book¹ of nearly seven hundred pages by two highly qualified clinicians and teachers. The authors find from statistical surveys of the leading causes of disability and death, that approximately two hundred diseases account for 98 per cent of all the disability in this country.

In the first section of the book, one finds a detailed analysis of 16 common symptoms, 33 leading physical abnormalities, and 6 essential laboratory tests which will serve as keys to the differential diagnosis of these two hundred diseases. A limited number of additional procedures are recommended to confirm the indicated diagnosis.

In part II the common symptoms of disease are each considered separately from the standpoint of

elicitation, pathologic physiology and differential diagnosis indicated.

The chapters in part III include the physical findings of inspection, auscultation and palpation. Various lesions of the skin, eye, oral mucous membrane, and uterine cervix are illustrated in excellent colored plates.

Part IV is devoted to the diagnostic implications of the small number of essential laboratory procedures.

Part V describes the differential diagnosis of the statistically important diseases grouped by anatomic regions.

There is no royal road to accurate diagnosis, and this book is not a substitute for standard medical works. As a text to read one soon becomes lost in a maze of charts and outlines. As a reference book for the practicing physician, it is the finest this reviewer has encountered. Printed on high quality paper in two columned bold type, it is easy to read and extremely practical in application.

EDWARD W. GUNN.

AS stated in the preface to *The Pathology of Traumatic Injury*² by James V. Wilson the author's aim has been to draw up in one place a summary of the pathological effects of trauma, stating that his work is not to be considered a complete catalogue of the literature upon this subject, but "has been produced during the stress of war while the author has been abroad." This apology seems superfluous when it is found that the reference number 555 titles. However as he states "the work is complete enough for the physician or surgeon, returning from the war anxious to apply the lessons learnt to the treatment of accident cases and it may be a guide to rational treatment."

The text is divided into two parts: the first dealing with the general and specific reactions of the body to various types of trauma while the second considers the special morbid anatomy and physiology of regional injury. The meat of the volume lies in the author's successful correlation of the experiences of the two wars with the scientific studies and clinical reports that appeared between the two conflicts. Unfortunately due to early publications of this work after the second war the many valuable studies of that period have had to be omitted. However the author's own vivid description of his observations upon the pathological material of the last war are valuable and extensive.

He correctly states that the mass of evidence favors the hematogenic theory of shock, there being no incontrovertible evidence in favor of nervous impulses themselves initiating the shock state. The essential pathogenic alteration is reduced cardiac output and blood flow vasoconstriction thrombosis, and hemoconcentration—all of which result in poor venous return, low blood pressure, further cir-

¹DIAGNOSIS IN DAILY PRACTICE: An Office Routine Based on the Incidence of Various Diseases. By Benjamin V. White, M.D., and Charles F. Geschickter, M.D. Philadelphia, London, and Montreal: J. B. Lippincott Co. 1917.

²THE PATHOLOGY OF TRAUMATIC INJURY. General Review By James V. Wilson, M.D., M.R.C.P. (London), Major, R.A.M.C. (T.). Baltimore: The Williams & Wilkins Co., 1944.

culatory stagnation and the vicious circle of anoxia diminished and abnormal metabolism and circulatory collapse. The reversibility of this cycle for only a certain period is essential in understanding the treatment. Whole blood is properly given the paramount place of importance in treating most types of shock, but plasma, saline and glucose solutions are also recognized to be of value if correctly used in proper proportion to blood to make up the specific deficits in various types of injury. The application of external heat in undue quantities is deprecated the comfort of the patient being stressed. Properly, little mention is made of opiates in the treatment of shock. These substances are unnecessary in profound shock, their indication being to combat restlessness and discomfort in the early phases of conditions likely to lead to shock.

The pulmonary, renal, hepatic, and special organ damages in each type of traumatic injury are extensively described and the special alterations in treatment indicated by these findings are given. For example in burns the profound effects of the complications of infection, anoxia, and marked nitrogen loss are stressed while in the crush syndrome the renal lesions are stressed and in blast injury the pulmonary and abdominal visceral changes are described in detail. The excessive administration of fluid into the venous side of the circulation in these latter two conditions is likely to be dangerous. Up-to-date chapters are included on fat embolism and on wounds and wound infections.

Injuries to the chest, the abdomen, the central nervous system and to the blood vessels command special chapters. It is in these fields that special advances have been made during the past conflict. However much of this newer knowledge has been a reorientation based on the observation of a large and varied material.

The only specific shortcoming in this small volume is an attempt to cover injuries to bones and joints in a small chapter of ten pages. The complications of fractures are described in slightly more than two pages of this chapter. This lack of space occasionally causes the author to lean too heavily upon the experiences of the second World War. An example is the following quotation, which is the closing sentence of the book: "These (the problem of joint resection for motion vs immobilization in treating damaged joints) and other problems may be settled when the final story of the recent war comes to be written."

The author is to be congratulated upon his terse direct style so often found in British monographs.

This small but remarkably well organized volume will be of value to anyone wishing an up-to-date view of the subject of traumatic shock or of the experiences of an expert pathologist with a voluminous material arising from the second World War. It would be difficult to condense the subject material further.

PAUL H. HARMON

A REMARKABLE account of the development of medical research in America, *American Medical Research: Past and Present*,¹ was written by a non-medical historian who has made the history of medical research his specialty.

The field is divided into four epochs. The first or British Colonial epoch, extends to 1820. The second epoch is the result of French influence extending from 1820 to 1860. The third epoch is the result of German influence and extends from 1860 to the end of the century and the fourth epoch in the twentieth century, is independent of any special outside influence. The first and second epochs are in the main devoid of experimental methods which were first imported by Americans who worked in the German clinics and laboratories during the second half of the nineteenth century.

With the remarkable advances in American medical research during the present century has come the construction of great medical centers by both the privately endowed and the state supported universities and, in a few instances the establishment of independent institutes of medical research. An extensive and accurate review of research activities is given in the various branches of preclinical and clinical medicine and the significance of the use of the basic sciences of chemistry and physics in both animal experimental and clinical investigation is pointed out.

It is predicted that there will be greater federal support for medical research in the future because of the outstanding advances made by the use of federal grants during the late war. It is pointed out that just as great emergencies exist in peace time as in war time, and that public opinion would sanction federal support of research against diseases such as cancer which accounts for about four hundred deaths daily.

The book is written without bias and should be worth while reading for everyone engaged in the field of medical research.

DALLAS H. PHENIXTER

AMERICAN MEDICAL RESEARCH, PAST AND PRESENT. By RICH and H. SHRYOCK, Ph.D. New York: The Commonwealth Fund, 1947.

CLINICAL CONGRESS OF AMERICAN COLLEGE OF SURGEONS

ARTHUR W ALLEN *Boston President*

DALLAS B PHEMISTER, *Chicago President Elect*

PRELIMINARY PROGRAM FOR 1948 CLINICAL CONGRESS

THE BILTMORE HOTEL LOS ANGELES

OCTOBER 18 TO 22, 1948

PLANS are proceeding for the program of the thirty fourth Clinical Congress of the American College of Surgeons which will be held in Los Angeles at the Biltmore Hotel from October 18 to 22 1948

Representatives of the Los Angeles hospitals which will participate in the clinical program have been holding meetings to further the scheduling of clinics in as nearly final form as possible. A preliminary schedule of clinics, preceded by a list of the hospitals which will participate and the names of the representatives who are responsible for the program at each hospital, follows this article. Twenty five hospitals have so far indicated a desire to participate, and they will arrange their programs to cover subjects in general surgery obstetrics and gynecology fractures, orthopedic surgery thoracic surgery neurosurgery genitourinary surgery and ophthalmology and otorhinolaryngology. Revised schedules will appear next month, and in succeeding months, up to the time of the Clinical Congress. During the Congress Daily Clinical Bulletins will be issued which will give the final clinical program.

The possibility of telecasting operations from one or more of the hospitals is still being explored. The use of television is especially desirable after the exceedingly successful demonstration of its teaching value at the Clinical Congress in New York last year.

The usual varied and comprehensive program of meetings at the headquarters hotel is planned. The opening session will be a General Assembly for both surgeons and hospital personnel on Monday morning. Scientific sessions, official meetings, and hospital conferences will follow during the five-day Congress. In addition to meeting rooms in the Biltmore Hotel, the Biltmore Theater and

the spacious Philharmonic Auditorium across the street from the hotel will be used for the larger audiences. The capacity of the Philharmonic Auditorium is 3 700 and that of the Biltmore Theater about 1 700.

PRESIDENTIAL MEETING

The opening evening session of the Clinical Congress will be devoted to the Presidential Meeting, at which the officers-elect, consisting of Dr Dallas B Pheminster of Chicago as president, Dr Howard A. Patterson of New York as first vice president, and Dr Carl H. McCaskery of Indianapolis as second vice president will be installed. Dr Arthur W Allen of Boston, outgoing president and vice-chairman of the Board of Regents, will preside and will deliver the Presidential Address. The third Martin Memorial Lecture will be delivered by Dr Clarence Crafoord, Professor of Surgery University of Stockholm.

CONVOCATION

The annual Convocation will be held on the final evening, Friday. The formal initiation ceremonies and the presentation of the Fellowship Address by Dr L. A. DuBridge, President, California Institute of Technology Pasadena, will constitute the program. Dr DuBridge's subject will be "The Physician Meets the Doctor."

EVENING SCIENTIFIC SESSIONS—GENERAL SURGERY

"Malignant Lesions of the Thyroid Gland" will be the subject of the Tuesday evening symposium on general surgery. "Pathology" will be discussed by Dr Frank W Foote of New York. "Aberrant Thyroid" by Dr Brien T King of Seattle. "Malignancy in Nodular Goiter" by Dr Warren H. Cole of Chicago and "Radioactive

Iodine in the Treatment of Thyroid Diseases Including Cancer by Dr Myron Prinzmetal, Los Angeles.

Endometriosis will be the subject of the Wednesday evening symposium on general surgery. Three speakers, among them Dr Joe V Meigs of Boston, will discuss, respectively **Significance of Endometriosis**, **Surgical Treatment of Endometriosis**, and **Theories and Medical Treatment of Endometriosis**. The **Fracture Oration** will also be presented at this session.

Surgery of the Heart and Great Vessels will be the subject of the Thursday evening symposium on general surgery. **Surgical Treatment of Pulmonic Stenosis** will be discussed by Dr Alfred Blacklock of Baltimore. **Surgical Treatment of Constrictive Pericarditis** by Dr Emile F Holman of San Francisco. **The Surgery of Patent Ductus Arteriosus** by Dr John C Jones of Los Angeles and **Treatment of Coarctation of the Aorta** by Dr Robert E Gross, Boston.

EVENING SCIENTIFIC SESSIONS—OPHTHALMOLOGY

The preliminary program for the Tuesday evening session on ophthalmology comprises the following three subjects: **Tumors of the Eyelids and the Conjunctiva**, **Partial Keratoplasty** and **Further Studies of the Cytology of Conjunctival Exudates**.

The Wednesday evening program will be devoted to a panel discussion on the subject, **Neoplasms of the Orbit and Nasal Accessory Sinuses** and will be participated in jointly by ophthalmologists and otorhinolaryngologists.

Subjects for the Thursday evening session have not yet been definitely selected.

EVENING SCIENTIFIC SESSIONS OTORHINOLARYNGOLOGY

The preliminary program for the Tuesday evening session on otorhinolaryngology comprises the following four subjects: **Suspension Laryngoscopy**, **"Effects of Streptomycin on Eighth Nerve Function"**, **Anatomical Considerations of the Temporal Bone**, and **Chronic Laryngeal Stenosis**.

The Wednesday evening program as stated under Ophthalmology will be on the subject **Neoplasms of the Orbit and Nasal Accessory Sinuses**, and will be a joint session with the ophthalmologists.

Four subjects have been selected for discussion at the Thursday evening meeting as follows: **Repair of the Facial Nerve**, **Surgical Considerations of the Physiology of the Nose**, **Tumors of the Nasopharynx**, and **The Role of Pregnancy in Otosclerosis**.

GENERAL SURGERY PANEL DISCUSSIONS

General surgery panel discussions will be held on Monday, Tuesday and Wednesday afternoons, from 1:30 to 3:00 and from 3:30 to 5:00 o'clock, and on Thursday afternoon from 3:30 to 5:00. The early session on Monday will be on **Acute Renal Failure in Surgical Patients**, with Dr Frederick A. Collier of Ann Arbor as moderator and the late session on **Tumors of the Mouth, Jaw and Face**, with Dr Gordon B New of Rochester Minnesota, as the moderator. The early session on Tuesday will be on **Low Lying Malignant Lesions of the Bowel**, with Dr Fred W Rankin of Lexington, Kentucky as moderator and the late session on **Evaluation of Liver Function in Relation to Surgery** with Dr Nathan A Womack Iowa City as moderator. The early session on Wednesday will be on **Peripheral Arterial Disease** with Dr Alton Ochsner of New Orleans as moderator and the late session on **Ulcerative Colitis** with Dr Henry W Cave of New York as moderator. The Thursday session will be on **Isotopes in Surgery** with Dr George M Curtis of Columbus as moderator.

OPHTHALMOLOGY PANEL DISCUSSIONS

Panel discussions in ophthalmology will be held Tuesday Wednesday and Thursday mornings from 9:00 to 10:30 o'clock. The Tuesday subject will be **Surgical Management of (1) Acute Inflammatory Glaucoma (2) Chronic Simple Glaucoma (3) Congenital Glaucoma**. The Wednesday subject will be **Congenital Cataract**. The Thursday subject will be **Surgery of the Oblique Muscles**.

OTORHINOLARYNGOLOGY PANEL DISCUSSIONS

Panel discussions in otorhinolaryngology will be held Tuesday Wednesday and Thursday mornings from 10:45 to 12:15 o'clock. The Tuesday subject will be **"Rehabilitation of the Hard of Hearing"** with Dr Walter P Work of San Francisco as moderator. The Wednesday subject will be **The Preparation of the Surgical Patient and Postoperative Care** with Dr Colby Hall of Los Angeles as moderator. The Thursday subject for discussion will be **Diseases of the Esophagus** with Dr Alden H Miller of Los Angeles as moderator.

SPECIALTY PANEL DISCUSSIONS

Specialty panel discussions will be held on Friday afternoon from 1:30 to 3:00 and from 3:15 to 4:45 o'clock, as follows:

Urology—Moderator Dr Reed M Nesbit, Ann Arbor

1 30 to 3:00 p.m.—“The Clinical Management of Branched Renal Calculi.”

3:15 to 4:45 p.m.—“Present Day Management of Urinary Tract Infections.”

Orthopedic Surgery—Moderator Dr John C. Wilson, Los Angeles

1 30 to 3:00 p.m.—“Mechanical Derangements of the Knee Joint.”

3 15 to 4:45 p.m.—“Fractures About the Hip.”

Thoracic Surgery—Moderator Dr Frank S. Dolley, Los Angeles

1 30 to 3:00 p.m.—“Diagnosis and Surgical Treatment by Pulmonary Resection for Carcinoma, Bronchiectasis, and Tuberculosis.”

3 15 to 4:45 p.m.—“Surgery of the Esophagus.”

Plastic Surgery—Moderator Dr Truman G. Blocker Jr, Galveston

1 30 to 3:00 p.m.—“Congenital Facial Deformities.”

3 15 to 4:45 p.m.—“Burn Contractures of the Extremities.”

Gynecology and Obstetrics—Moderator Dr John C. Burch, Nashville

1 30 to 3:00 p.m.—“Hysterectomy Physiological Considerations—Indications.”

3 15 to 4:45 p.m.—“Hysterectomy Technical Considerations—Complications.”

Neurological Surgery—Moderator Dr Howard C. Naffziger, San Francisco

1 30—“Cerebral Angiography.”

FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

The Forum on Fundamental Surgical Problems, one of the most popular features of Clinical Congresses during the past few years, will be held on Tuesday through Friday mornings, in two sections meeting concurrently. Brief reports of original clinical and experimental observations relating to the broad aspects of surgery and the surgical specialties will be presented under the general direction of Dr Owen H. Wangensteen, chairman of the committee, Forum on Fundamental Surgical Problems.

HOSPITAL CONFERENCES

The opening meeting of the twenty-seventh Hospital Standardization Conference will constitute the first formal session of the Clinical Congress, and will be a General Assembly for both surgeons and hospital representatives. Dr Arthur W. Allen of Boston, President of the College, will preside. The hospital conferences will continue on Monday afternoon, with sessions following on

Tuesday, Wednesday and Thursday mornings, afternoons and evenings.

Hospital trustees, administrators, heads of the various hospital departments and their personnel nursing groups, and many other persons directly or indirectly concerned about hospital progress, are invited to participate in the discussions at the hospital conferences, at which leaders in the hospital field are the speakers and the moderators. The meetings will include formal sessions, panel discussions, round table conferences, symposia, and forums.

A meeting which is always of great interest to hospital administrators and members of medical staffs in hospitals, as well as to surgeons, is the symposium on graduate training in surgery which is scheduled for Thursday afternoon after the annual meeting of Fellows.

COMMITTEE ON ARRANGEMENTS

The Committee on Arrangements for the Clinical Congress in Los Angeles has been well organized and is actively functioning. The membership follows:

General Committee

Donald G. Tollefson, M.D. F.A.C.S., *Chairman*
Hugh T. Jones, M.D. F.A.C.S., *Vice-Chairman*
Harold Lincoln Thompson, M.D. F.A.C.S., *Secretary*
Treasurer
Gilbert J. Thomas, M.D. F.A.C.S., *Represent of the College*
E. Vincent Askey, M.D., F.A.C.S.
Max W. Bay, M.D. F.A.C.S.
J. MacKenzie Brown, M.D. F.A.C.S.
Lawrence Chaffin, M.D. F.A.C.S.
A. Ray Irvine, M.D. F.A.C.S.
Maurice Kahn, M.D. F.A.C.S.
W. E. MacIntosh, M.D.
B. O. Raulston, M.D.
Louis J. Regan, M.D.
Carl Roemer, M.D., F.A.C.S.
Stafford Warren, M.D.

Committee for the Southern California Chapter

Ray B. McCarty, M.D. F.A.C.S., *Riveride*
Meredith G. Beaver, M.D. F.A.C.S., *Redlands*
Clarence E. Rees, M.D. F.A.C.S., *San Diego*
Carl G. Johnson, M.D. F.A.C.S., *Long Beach*
James H. Saint, M.D. F.A.C.S., *Santa Barbara*

Hospital Committee

The members of the hospital committee are listed with the list of hospitals participating in the clinical program which precedes the preliminary schedule of hospital clinics later in this article.

MEDICAL MOTION PICTURES

An appreciated feature of the Clinical Congress will again be the showing of medical motion pictures each day. The latest available pictures on

surgery and related subjects will be presented. Special showings will be arranged of medical motion pictures in the fields of ophthalmology and otorhinolaryngology. Both sound and silent films will be shown all of which will have been approved by the Committee on Motion Pictures. Some of the newer medical motion pictures now under production will be shown.

TECHNICAL AND SCIENTIFIC EXHIBITION

The Technical and Scientific Exhibits will occupy the Ballroom foyer, the Renaissance Room and the Galleria of the Biltmore Hotel, according to present plans. Leading manufacturers of surgical instruments, x ray apparatus, sterilizers, operating room lights, ligatures, dressings, hospital apparatus and supplies of all kinds, and pharmaceuticals, and publishers of medical books will be represented.

ADVANCE REGISTRATION

Surgeons who wish to attend the Congress should register in advance. Under a new plan, advance registration will greatly expedite the procedure of registering. No registration fee will be charged Fellows whose dues are paid to December 31, 1947. For endorsed Junior and Senior Candidates, the fee will be \$5.00. Non Fellows who after individual consideration are permitted to register, will pay a fee of \$10.00. No registration fee will be required of initiates of the class of 1948.

HOTEL RESERVATIONS

It is desirable to make hotel reservations as early as possible because of the shortage of hotel rooms that prevails in Los Angeles as well as in other cities. In making these, communications should be addressed to the Los Angeles Convention and Visitors Bureau care of the Los Angeles Chamber of Commerce, stating that you will be attending the Clinical Congress of the American College of Surgeons. All hotel reservations for the Clinical Congress are to clear through this Bureau. No correspondence should be sent direct

ly to the hotels. A form for reservations was enclosed in the letter recently sent to Fellows. Choice of hotels may be designated. The hotels in Los Angeles require a deposit in advance.

There follows the list of member hotels. Convention and Visitors Bureau, Los Angeles Chamber of Commerce.

AMERICAN COLLEGE OF SURGEONS APPROVES USE OF NURSE ANESTHETISTS

THE Board of Regents of the American College of Surgeons, at a meeting on February 22, 1948, adopted a resolution commending the services of nurses who have had special training in the administration of anesthesia and recommending the continuance of training courses in this field for nurses. The resolution reads as follows:

The American College of Surgeons regards with deep concern the actions of some physician anesthesiologists in giving the impression to the laity in the public press that it is unsafe for experienced nurse anesthetists to conduct surgical anesthesia. While it supports the increasing tendency of having physician anesthesiologists in charge of surgical anesthesia, it deplores at this time any propaganda for the elimination of the trained nurse anesthetist. On the contrary, the American College of Surgeons is of the opinion

that in view of the inadequacy in number of the physician anesthesiologists and in view of the splendid record of achievement of the nurse anesthetists, institutions engaged in the training of nurses for this purpose should be encouraged to continue their programs.

In its *Manual of Hospital Standardization* the American College of Surgeons states with respect to personnel in the Department of Anesthesia:

"The personnel in the Department of Anesthesia must consist of trained, competent assistants. Nurse anesthetists who have specialized in the administration of anesthetics are usually competent and acceptable for the work, but since they are not physicians licensed to administer drugs, they should be under medical supervision. If it is impossible to obtain or maintain a specially trained anesthetist in the community, a member of the medical staff, who has had experience in anesthesia, might assume the responsibility for supervision and direction of the department of anesthesia."

SUBJECT INDEX TO VOLUME 86

ABDOMEN diseases of Esophagitis, ed. 373 Combined
perineal and abdominal operation for repair of rectal
prolapse, 493 distention of Atypical adynamic ileus
apparently caused by nutritional (thiamine chloride)
block IV Investigation of intestinal dyskinesia, co-
lonic atony and visceral afferent fibers, 571 Clinical
study of effect of intercostal nerve block with nup-
ercaline in all following upper abdominal surgery 680;
Various types of diaphragmatic hernia treated surgi-
cally, report of 430 cases, 735

Abnormalities, Congenital anomalies, ed. 247 Congenital
anomalies of female reproductive organs, ed. 249 con-
genital, Hypopspadias with enlargement of prostatic
utricle, 307 congenital, Repair of hypopspadias with
free iliac skin graft, 439 congenital, Primary closure
of hernia, ed. 504 Congenital, atresia of intestine and
maternal hernia treated surgically report of 430 cases,
735 congenital, Surgical treatment for coarctation
of aorta, ed. 756 Congenital pulmonary stenosis,
ed. 758

Abcesses, of brain Radical treatment of 230 of lung, Pul-
monary resection for 385

Alcoholism Atypical adynamic ileus apparently caused by
nutritional (thiamine chloride) deficiency report of
6 cases, 543

Amblyopia early Steel wire sutures, local anesthesia and
immediate, in treatment of hernia 530 early Wound
healing in, 565

American College of Surgeons—
Approves use of nurse anesthetists, 774
Clinical Congress, Forum of Fundamental Problems
for surgical specialists, 512 Challenge of surgical forum
ed. 631 Preliminary plans for 648 Biltmore Hotel,
Los Angeles, October 18 to 21 1948 638 Participation
in Forum on Fundamental Surgical Problems, 640
Preliminary program for 1948 Biltmore Hotel Los
Angeles, October 18 to 21 760

Anatomy, teaching of Congenital anomalies, ed. 247
bronchial arteries, anatomic study of 150 cadavers, 395
Anesthesia, local Steel wire sutures, and immediate am-
blyopia in treatment of hernia, 530, Differential spinal
block IV Investigation of intestinal dyskinesia, co-
lonic atony and visceral afferent fibers, 571
Anesthetics, nupercaline in all Clinical study of effect of
intercostal nerve block with following upper abdomi-
nal surgery 680

Anesthetist, Nurse physician ed. 1 5, nurse American Col-
lege of Surgeons approves use of 774
Anomalies see Abnormalities
Antibiotics, Topical use of in established surgical infec-
tions, ed. 760

Anus, Surgical treatment of chronic anal fissure, 434
Aorta, Surgical treatment for coarctation of ed. 756
Aortic valves, Aortic valvulotomy experimental methods
and early results, 513

Arm, Neurovascular complications from malposition on
operating table, 730

Arteries, ureteral, Study of ureteral blood supply and its
bearing on necrosis of ureter following Wertheim oper-
ation 36 Bronchial anatomic study of 150 cadavers,
395 pulmonary Congenital stenosis, ed. 758
Atomic Energy Commission, Use of isotopes in surgical
research, 129

Atresia, Congenital, of intestine and colon, ed. 504

BARTHOLIN cyst, simple method for its restoration to
function 359

Bile, reflux into pancreatic duct, Surgical treatment of re-
current acute pancreatitis by endocholedochal sphinc-
terotomy 205

Bile duct, Electrocardiogram in biliary tract disease and
during experimental biliary distention clinical obser-
vations on 16 patients, 617

Biological chemistry of wound healing I Effect of di-
methionine on healing of wounds in protein-depleted
animals, 583

Biology, Use of isotopes in surgical research, 129
Blood, Experimental study on lipoclastic 341 transfusion
Contributions of animal experimentation to treatment
of surgical shock, 487 transfusion, Correction of hypo-
proteinemia by administration of plasma and, 604

Blood vessels, Influence of vitamin E on vascular disease, 1
Study of ureteral blood supply and its bearing on
necrosis of ureter following Wertheim operation 36

Flow upon gastric secretion and prevention of gastric blood
mental peptic ulcers, 164 Causalgia II. Signs and
symptoms, with particular reference to vasomotor dis-
turbances, 452 Experimental study of comparative
efficacy of heparin and dicumarol in prevention of arte-
rial and venous thrombosis, 687 Neurovascular com-
plications from malposition on operating table 720

Surgical treatment for coarctation of aorta ed. 756
Congenital pulmonary stenosis, ed. 758

COLLECTIVE REVIEW

THE INCIDENCE OF GASTRIC CANCER

GEORGE T. PACK, M.D., and GORDON McNEER, M.D. New York, New York

IN evaluating the incidence of gastric cancer a distinction must be made between the actual occurrence of the disease and the recorded morbidity. Many factors contribute to a disparity between the two particularly on a world wide level. Differences in diagnostic techniques, dissimilar statistical methods and inequalities in the status of public health education and medical care challenge the validity of both international comparisons of incidence rates and regional comparisons within a single country.

Cancer is not for the most part a reportable disease with the result that no all inclusive figures on its occurrence are available; the most reliable indices remain mortality records and institutional reports. Since death rates take no cognizance of cured or undiagnosed cases, they obviously understate the true incidence.

No other nation moreover issues classified data on the mortality from gastric cancer comparable to those in the United States Vital Statistics. In Western Europe information stems mainly from hospital reports and the compilations of individual physicians. The further one goes from the centers of western civilization the more haphazard statistical methods become in large areas of the world the sole sources of intelligence are isolated missionaries and physicians recording their observations without benefit of organizational facilities.

Until recently even in this country there was no statistical separation of cancer of the stomach; it was common practice to group it with malignant tumors of the liver, peritoneum and other gastrointestinal sites. Since virtually all intra-abdominal

and many extra-abdominal cancers metastasize to the liver this gave an ambiguous picture of the frequency of gastric carcinoma alone.

It is obvious that accurate incidence rates are impossible without correct diagnosis. For cancer of the stomach the standard antemortem procedure employs the barium meal followed by expert fluoroscopic and roentgenographic examination. Following the first gastrointestinal study by means of a barium-contrast meal in 1904 (47) the reported incidence of gastric cancer in the United States increased sharply until 1925. Then as diagnostic techniques became more standardized and statistical methods more precise the curve leveled out and even dropped slightly.

Similar clarification has yet to take place in those parts of the world where modern medical techniques have not yet penetrated or are unavailable to a large proportion of the population. Even in the United States there is a striking dissimilarity in the reported incidence for states enjoying a high level of medical care and those with inhabitants who are too poor, too ignorant or too neglected to obtain diagnosis and treatment of the symptoms referable to gastric carcinoma.

It is obviously impossible to draw definitive conclusions on the basis of present data. Nevertheless, such statistics as are available contribute to our knowledge of the incidence of the disease and can not be ignored.

SEX

Cancer of the stomach occurs more commonly in men than in women. In the United States, of the 26,135 persons who died of the disease in 1940 16,111 or 61.6 per cent, were males and 10,024 or 38.4 per cent, were females (58). They represented

From the Gastric Service of the Memorial Hospital, New York, New York.

TABLE I.—SEX DISTRIBUTION OF GASTRIC CANCER

Hospital and period	Total cases	Males		Females	
		Number	Per cent	Number	Per cent
Mayo Clinic, 1907-1933 (6)	2,399	1,560	78.7	1,374	57.9

Memorial Hospital, New York, 8-1915	1,200	8	68.3	73	51.3

21.4 per cent of the total cancer deaths among men and 12.1 per cent among women.

Great Britain exhibited a similar ratio of male preponderance (19). Of 13,402 fatalities from gastric carcinoma in England and Wales in 1940, 7,455 or 55.6 per cent, occurred in males and 5,947 or 44.4 per cent, in females. The stomach was the primary site of these cancers in 21.9 per cent of the men and in 16.1 per cent of the women.

Germany (16) revealed a like distribution, with 55.1 per cent of a total of 35,317 fatalities in men. In Australia (3) the percentage of male mortality was higher (61.3%).

The three-to-two ratio of male preponderance finds support in a series of 40,573 fatalities recorded by the Metropolitan Life Insurance Company over a 16 year period from 1917 to 1933 (9). This study showed a 30 to 50 per cent higher incidence rate among men. Moreover gastric neoplasms caused a total of twice as many cancer deaths among males as among females.

Many hospital reports throughout the world (Table I) reveal a greater difference in sexual inci-

dence, citing a two-to-one and even three-to-one ratio. The former figure finds corroboration at the Presbyterian Hospital, Chicago, and the Surgical Clinic of the University of Leipzig the latter at the Mayo Clinic, Rochester, Minnesota and Johns Hopkins Hospital, Baltimore. At the Memorial Hospital, New York, 68.6 per cent of the 1,100 cases studied from 1916 through 1946 occurred in males. A masculine incidence of 58.8 per cent at the College of Physicians and Surgeons, Baltimore, more closely approaches the proportion found in vital statistics.

AGE

Cancer of the stomach is primarily a disease of middle and late life, occurring most frequently between the fiftieth and seventieth years. Thus, in 1940 only 10.1 per cent of the deaths therefrom in the United States took place prior to the age of 50 in Great Britain and Wales 9.5 per cent in Germany 8.6 per cent and in Australia, 7.5 per cent. The Memorial Hospital series reveals a substantially larger proportion (27.1%) of patients under 51 years of age. The disparity may be due to the fact that vital statistics take cognizance only of fatalities.

This age factor is highly significant, predisposing to a greater incidence wherever life expectancy exceeds the fifth decade. In the United States, for example, with 20.4 per cent of the population over 50 years of age in 1940 (57) the death rate from gastric cancer was 10.8 per 100,000. Similar data for twenty representative states revealed, almost without exception, a high mortality in those with a large group of individuals over 50 years of age in contrast to a conspicuously lower rate in those where longevity was less (Table II).

These figures support less precise reports from other countries. In England and Wales, France, Germany, Norway, the Netherlands, and Australia, where a substantial proportion of the population lives for more than half a century, a high incidence of gastric cancer is reported. It is reputedly less common in such countries as the Union of Soviet Socialist Republics, Bulgaria, Rumania, and India, where fewer than 15.5 per cent of the population survive the fifth decade. Japan is an exception to this correlation between longevity and incidence with a relatively high mortality rate although only 15.3 per cent of its inhabitants reach the age of 50 (20). Nevertheless, it is safe to assert that if standardized statistics were available for the entire world, they would show a demonstrably higher incidence of gastric cancer wherever 20 per cent of the population or more attain the sixth decade of life.

Fatalities reach their highest level between the sixty-fifth and seventieth years. In 1940 16.7 per cent of all deaths from cancer of the stomach in the United States took place in this quinquennial period. In Germany the corresponding figure for the same age group was 19.7 per cent, and in England and Wales, 18.7 per cent. In all three countries the mortality peak occurred later for women than for men, i.e. between the seventieth and seventy-fifth years. This was the period of greatest fatality (19.7 per cent) for males as well as females in Australia, with the feminine crest persisting through the seventy-ninth year (Table III).

The high death rate after age 75 is noteworthy. In the United States 23.8 per cent of the total deaths from gastric carcinoma were in this advanced age group. In Germany, 19.3 per cent in England and Wales, 20.5 per cent, and in Australia, 25.8 per cent. There was a distinct preponderance of women in this category, due no doubt to their greater longevity.

However, the disease is by no means confined to the upper age brackets (Table III). In 1940 4.7 per cent of the deaths from cancer of the stomach in the United States took place in patients from 30 to 44 years old, 12.8 per cent in patients from 45 to 54 years old, and 24.8 per cent in patients from 55 to 64 years old. The corresponding figures for England and Wales were 4.6, 12.1, and 24.8 per cent; for Germany 4.4, 10.5, and 27.3 per cent; and for Australia 2.8, 11.0, and 23.2 per cent.

Even in the young, cancer of the stomach is not unknown. In 1940 the percentage of deaths in patients under 30 years of age was 0.6 in the United States, 0.4 in England and Wales, 0.3 in Germany, and 0.4 in Australia.

Clinical reports, based on morbidity rather than mortality, suggest a slightly higher incidence (17.34-39). Of 1,193 cases at the Memorial Hospital, 10 or 0.8 per cent occurred in pa-

tients under 31. At the Mayo Clinic (61) the ratio in this age group ranged from 0.8 to 1.4 per cent, and at the Presbyterian Hospital, Chicago, it was 1.2 per cent. Other institutional data (41, 12, 51) cite a morbidity for the first three decades of life of approximately 8 per cent in the total number of cases.

Gastric carcinoma is extremely rare in childhood. Between the fifteenth and thirtieth years, however, the incidence rises sharply in each successive 5 year period, with more than half of the cases occurring between the ages of 25 and 30. In 1942 501 proved cases of gastric cancer in patients under 31 years of age were collected from

	15-85 years 30-86 years 17-79 years	57 years 57 years 55.9 years

the literature (34). In this group there was equal distribution between the sexes, which is in contrast to the predominance of males in the older age groups.

The incidence by age classes, in 1,193 cases of gastric neoplasms studied at the Memorial Hospital over a 30 year period does not correspond to that depicted in the United States and in other vital statistics (Table IV). In our cases the morbidity crest (19.3%) for both sexes occurred earlier from 61 through 65 years of age. The entire incidence prior to age 66 was greater with 13.2 per cent of the cases in patients from 31 through 45, 28.8 per cent from 46 through 55, and 36.3 per cent, from 56 through 65 years. The incidence of patients past 75 years was small, only 1.8 per cent.

Other institutions with large series of cases report similar findings. At the Mayo Clinic, the College of Physicians and Surgeons, and Johns Hopkins Hospital, the decade of greatest frequency was from 50 to 60 years of age (Table V). The later crest in the vital statistics is probably explained by the interval between recognition of the disease and death. If so, this gap may be expected to widen as diagnostic and surgical methods improve.

RACE

Comprehensive data on the racial incidence of gastric carcinoma are as yet unobtainable, due to paucity of diagnostic and statistical facilities in those areas of the world where the non white peoples are concentrated. Thus, information on negro susceptibility treats exclusively of the American negro; there are no reliable figures on his African brothers. The Semitic peoples are represented only by European and American Jews. It would be hazardous to attempt broad inferences from such limited material.

Negroes

In 1940 the negro death rate in the United States from cancer of the stomach was reported as 14.4 per 100,000 compared to 20.4 for the white population (58). The accuracy of this figure is open to doubt because of the geographical distribution of our colored population: large numbers live in rural areas of the South where medical facilities are sparse and a low level of education and income tends to prevent recourse to professional care except in extremis. Even in cities they lack easy access to well trained general practitioners.

Nevertheless, there are some factors which confirm the relative infrequency of gastric carcinoma among negroes. Because of a higher infant mortality rate and a greater incidence of tuberculosis and other chronic infectious diseases, the negro's life expectancy of 53.85 years in the United States is considerably less than the white man's of 64.97 years (59). In 1940 only 14.5 per cent of the colored population had passed the fifth decade, compared to 21.1 per cent of the white (57). Thus, negroes do not as often reach the ages at which gastric neoplasms are prone to occur.

Will the lesser incidence among negroes persist as their life span lengthens? In the 16 year series presented by Dublin in 1936, the most striking rise in the crude death rate from gastric cancer occurred in colored males from 9.6 per 100,000 in 1917 to 20.6 in 1933. During the decade from 1930 to 1940 the increase in life expectancy was twice as great for the negro population as for the white (6% for males and 11% for females) (6). While there is undoubtedly a correlation between this greater longevity and higher incidence, the improved educational status of the negro and better opportunities for medical care must also be considered as possible contributors to the rise in the recorded mortality from gastric cancer.

An interesting phenomenon is the earlier age at which the disease appears in negroes and reaches its peak. Of 200 patients about equally divided between negroes and whites (38) almost half in the colored group developed cancer between 30 and 50

PACK, McNEER INCIDENCE OF GASTRIC CANCER

University of Michigan Hospital Ann Arbor Mich. 1930-1939 (46)	4.5	5-60 years	30	Over 70 years	0
Callie P. Huntington Memorial Hospital, Boston and Foodville Hospitals, Wrentham, Mass. 1922-1933 (40)	213	30-60 years	33.3	Under 30 years	0
Memorial Hospital, New York, 1916-1940	4.03	35-65 years	36.3	Over 60 years	33.3
				Under 35 years	8
				Over 70 years	7.5

years of age while little more than a quarter of the white group developed this condition during those decades. In the Metropolitan Life Insurance Company series the average annual negro death rate for cancer of the stomach exceeded the white in the age group from 25 to 44 years. This is corroborated by United States Vital Statistics for 1940. Whereas only 9.0 per cent of the mortality among whites occurred prior to age 50 the analogous figure for the colored population was 23.4 per cent (Table VI). One and one half per cent of the negro deaths occurred before the fourth decade compared to 0.4 per cent of the white. From 30 to 44 years, the respective percentages were 11.6 and 4.2 from 45 to 54, 25.0 and 11.9.

The peak of negro incidence also occurs at an earlier age. In 1940 16 per cent of the fatalities from cancer of the stomach among the colored population occurred between the ages of 60 and 64. For the population as a whole the 5 year period of maximum mortality (16.7%) was that from 65 to 69 years while the peak for whites alone (17.1%) lay between that from 70 to 74.

While Jews are not strictly speaking a race there are many factors which lend interest to the incidence of gastric carcinoma among them. One is their reputed susceptibility to the disease, often

attributed to their predilection for highly seasoned foods. Theoretically their adherence to prescribed customs for thousands of years, the segregation imposed upon them and their tendency to marry among their own people might have precluded racial tendencies.

Statistical studies for several European cities with a large Jewish population fail to demonstrate a greater incidence of cancer of the stomach among Jews (43). If anything the disease was shown to be slightly more prevalent among non Jews in Budapest, Amsterdam, and Berlin.

TABLE VI.—DEATHS FROM GASTRIC CANCER, WHITE AND NEGRO POPULATION UNITED STATES 1940

Age period	White		Negro	
	No.	Percent	No.	Percent
Total	24, 6	00	1, 248	00
30-44 years	1, 004	4	4	11.6
45-54 years	87	9	66	5
55-64 years	1, 015	4.1	513	8.0
Period of greatest frequency	70-74 years	7	60-64 years	6

In the first named (53) the incidence among the Jews from 1924 to 1927 was 35.6 per 100,000 as compared to 37.5 for non-Jews. A more significant deviation appeared in comparisons of the estimated populations of cancer age on this basis the rates were 105.3 per 100,000 for Jews and 140.3 for non-Jews.

Similar studies in Amsterdam for from 1922 to 1926 also revealed a greater frequency of gastric neoplasms among non-Jews, 47.8 per 100,000 as compared to 27.9 for Jews. From 1920 to 1929 the mortality among Hebrews was 34.8 per 100,000 for males and 31.2 per 100,000 for females, compared to a rate of 50.8 per 100,000 for males and 35.4 per 100,000 for females for the population as a whole (23).

Although comparable statistics are not available for Berlin, it may be of interest to note that in that city from 1932 to 1934, carcinoma of the stomach and duodenum caused 24.18 per cent of the total cancer deaths among Jewish men and 16 per cent among Jewish women (62). The corresponding percentages for the entire population were 35.88 for males and 24.78 for females.

At the Memorial Hospital, with an exception among the large Hebrew population to draw upon there were 531 Jews (44.3%) in our series of 1,200 cases of gastric neoplasm.

It is possible that an exaggerated impression of Jewish susceptibility to gastric carcinoma is created by their concentration in large cities with extensive institutional facilities. Certainly their interest in medical care and insistence on the best available services would tend towards a high percentage of diagnoses among them. Nevertheless actual figures show a slightly greater prevalence among non-Jews.

Primitive races

In a few selected regions of the East where institutional statistics are available the Chinese exhibit a relatively high morbidity from gastric cancer. In East Sumatra for example where Javanese and Chinese coolies live under similar conditions, the stomach was the site of only 1 per cent of all carcinomas among the Javanese in contrast to 19 per cent among the Chinese (53). Liver cancer on the other hand, constituted 55 per cent of all malignant tumors among the Javanese, compared to 28 per cent among the Chinese. In connection with these figures, it may be significant that gastric ulcer rare among the Javanese is common among the Chinese.

Similar observations were made in Java (5) Among the Malaysians of Batavia, cancer of the stomach did not figure among the common forms of carcinoma but malignant tumors of the liver

were frequent. The Chinese population, on the other hand displayed approximately the same ratio between the stomach and other sites as was found in the Western Hemisphere (29).

The higher incidence among the Chinese was evident also in a series of 654 specimens of cancer examined and tabulated by the Institute for Medical Research in British Malaya (22). Whereas cancer of the stomach constituted only 3.5 per cent of the total number of cases, it represented 5.3 per cent of the cases among the Chinese. The low rate for East Indians in this city (1.7%) corroborated other observations on the infrequency of the disease in South India and Ceylon, due perhaps to the short life expectancy there.

The comparatively high incidence among the Chinese is matched in Japan. This may reflect the greater literacy and better facilities for medical care in that country.

Turning to the North American continent, it may be worth recording Bishop Rowe's observation that he never saw a case of cancer of the stomach in his many years of missionary work among the Eskimos (48). Against this favorable observation must be placed the early age at which these people succumb to pulmonary tuberculosis.

DIET

On the basis of present knowledge diet offers few clues to the incidence of gastric cancer. Although the disease has been attributed to the consumption of hot, spicy foods, it is relatively infrequent in Mexico where hot tamales and chili are dietary staples. It is virtually unknown among the fish-eating Eskimos but common in Japan where also fish is an important part of the diet. On the other hand, the Japanese use large quantities of spices and partly decayed plant products (21).

In India, where cancer of the stomach is rare it occurs most often among the meat-eating Christians (24). It is considered one of the common types of carcinoma in Persia, where meat-eating is usual. In contrast to its alleged rarity among peoples given to a bland vegetarian diet.

There is a high incidence among Scandinavians. Germans, Hollanders and Jews all of whom are notorious overeaters, in contrast to a relatively low rate among the Russians who have been on short rations for the past 30 years. In sections of Germany (56) Austria (56) and Russia (43, 45) there was a definite increase in gastric carcinoma following the removal of the dietary restrictions imposed by World War I. yet in England the disease is said to be more common among the poor than the well-to-do (26). Moreover, the rate here is strikingly higher for North Wales, where the

diet is deficient in fresh milk and vegetables and leans heavily toward fried foods (6)

In evaluating these data, the short life expectancy among the Mexicans, Eskimos, Hindus and Russians must be taken into account.

GEOGRAPHIC DISTRIBUTION

Carcinoma of the stomach supposedly has its greatest frequency in the United States, Great Britain, Germany, Scandinavia, Holland, France, Switzerland, Czechoslovakia, Japan and Australia. It is reputedly less common in Russia, China, Mexico and South America and is virtually unknown among Alaskan Eskimos, Arabs, Indians, Afghans and African negroes.

Do these last-named peoples really enjoy immunity to cancer of the stomach? It is noteworthy that all of the areas with low incidence rates are regions where life expectancy is low and the facilities for recognition and registration of the disease poor. The recorded incidence for China, for example, is negligible, yet the rate for the Chinese in the Dutch East Indies is comparable to that in the Western Hemisphere. The Hindus exhibit a similar phenomenon with a low rate in India (24-35) and a much higher one in Dutch Guinea (55).

In other words, as hospital facilities are provided and reliable statistics become available a higher incidence of gastric carcinoma is manifest. Thus, in Korea 75 of 150 cases of operable neoplasms admitted to Severance Hospital Seoul were diagnosed as gastric cancer (31). An even larger percentage (53-36) was cited in a Japanese report on 28,015 cancer fatalities (20). In China carcinoma of the stomach was found in 4.7 per cent of the tumor cases admitted to hospitals in the various provinces (15).

At the Memorial Hospital 388 foreign-born patients with gastric carcinoma were seen in the 30 year period from 1916 through 1946 (Table VII). Their distribution, with respect to nation of origin did not fall into any of the prescribed patterns. Thus Mexicans, and Central and South Americans, who constitute only 1.4 per cent of the foreign-born population of New York City formed 2.8 per cent of the alien patients, although their native countries report a low incidence rate for cancer of the stomach. Great Britain, the Scandinavian countries and Germany on the other hand with reputedly high rates contributed less than their proportionate number. The striking disparity between the percentage of Russian patients and the size of the Russian population is probably due to the fact that most of the former were not ethnically Russians but Russian Jews. In a city such as New York the existence of hos-

TABLE VII.—COUNTRY OF BIRTH PATIENTS WITH GASTRIC CANCER SEEN AT THE MEMORIAL HOSPITAL NEW YORK, N.Y. 1916 THROUGH 1946 AND THE FOREIGN BORN POPULATION IN THE CITY OF NEW YORK, 1940

pitals dedicated to the services of specific national groups somewhat upsets the normal distribution of patients and makes it more difficult to correlate incidence to national origin. However this enhances, if anything, the disproportion between foreign born and native-born patients in our series. In 1940 the population of New York 7,454,995 was divided into 72.1 per cent native-born, of whom approximately half were of alien parentage and 27.9 per cent foreign born. Our 185 patients more than reversed this proportion with 74.9 per cent foreign-born patients to 25.1 per cent native-born.

DISTRIBUTION WITHIN THE UNITED STATES

In 1940 the crude death rate for cancer and other tumors in the United States was 125.2 per 100,000. The corresponding figure for gastric carcinoma was 19.8 with the greatest number of cases occurring in the Eastern, Northeastern, West Cen-

tral, North Central, and Far Western states and the fewest in the deep South¹ (Figs. 1 and 2).

If the crude death rate for malignant disease of the stomach is analyzed for various sections of the country it displays an unmistakable dependence upon life expectancy, the facilities for medical care and the general sociological level (Tables VIII-XII). Urban or rural life *per se* does not appear to influence the incidence of gastric carcinoma, but the poor hygienic, educational and economic conditions which prevail in certain rural areas, notably the deep South do. They militate against the long span of life favorable to the disease and against its detection when it occurs. Comparable conditions elsewhere in the world produce comparable results, i.e., a low imputed incidence which does not reflect the true frequency or potential frequency of the disease.

New England and North Atlantic states. (Vermont, Massachusetts, New York and Pennsylvania)

In the four states selected as a sample for this group the death rate for gastric cancer ranged between 21.2 per 100,000 for Vermont and 26.5 for Massachusetts. This was above the figure for the country as a whole, undoubtedly reflecting the high

degree of longevity and exceptional concentration of physicians (2), hospital beds (27) and medical schools (28) in this region (Table XIII). All four states fall in the two top categories for provision of medical care and have nineteen recognized medical schools within their boundaries.

Cancer of the stomach occurs with increasing frequency after the fifth decade of life. In 1940 the United States as a whole had an "over 50" population of 20.4 per cent. For the selected states the figure varied from 20.9 per cent in Pennsylvania to 24.4 per cent in Vermont. Compare this with 14.9 per cent for Alabama, 15.2 per cent for Mississippi, and 15.4 per cent for Georgia, and it is seen that far more people in the New England and North Atlantic states reach an age at which cancer of the stomach might be expected to occur.

With the exception of Vermont, the population of the selected states was overwhelmingly urban (57). In New York, 83.8 per cent of the population lived in the larger cities; in Massachusetts, 80.4 per cent; and in Pennsylvania 66.5 per cent. Vermont was alone with a rural population of 65.7 per cent.

It is interesting to compare the 21.2 per 100,000 death rate from gastric cancer for this state with the figure of 9.7 for Alabama, where 69.8 per cent of the population lived under rural conditions, and 9.9 for Georgia, with a rural population of 65.6 per

¹From the period from 1935 to 1940 to that from 1941 to 1945, the Metropolitan Life Insurance Company reported a drop of 6 per cent in its death rate from gastric cancer for all males, and 1.4 per cent for white females (26).

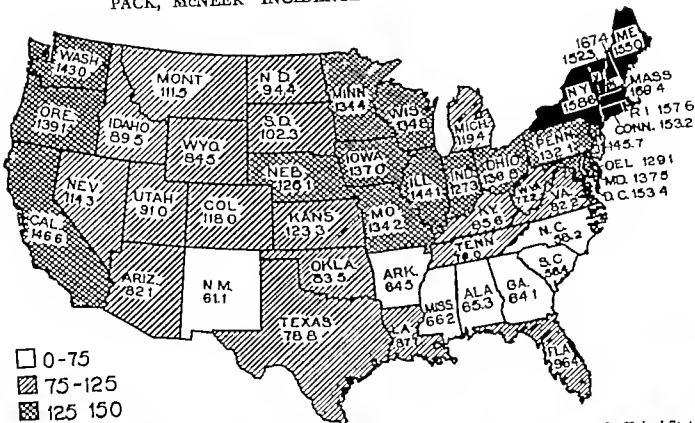

Fig. 1. Death rate from cancer and other malignant tumors (all types) in the United States, 1940. Crude death rates per 100,000 population

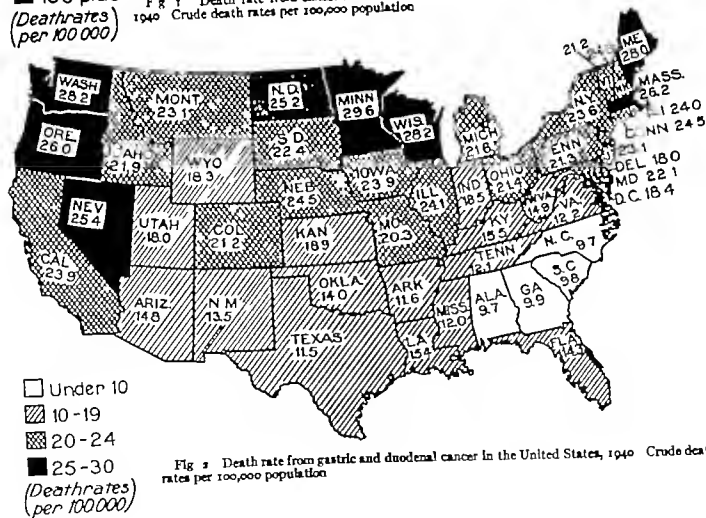

TABLE IX.—PER CENT OF URBAN POPULATION IN THE UNITED STATES 1940

Per cent of urban population	Number of states	States
65 per cent or more		California, Connecticut, Illinois, Massachusetts, Michigan, New Jersey, New York, Ohio, Pennsylvania, Rhode Island
50-64 per cent		Colorado, Delaware, Florida, Indiana, Maryland, Missouri, New Hampshire, Utah, Washington, Wisconsin
35-49 per cent	14	Iowa, Kansas, Louisiana, Maine, Minnesota, Montana, Nebraska, Nevada, Oklahoma, Oregon, Tennessee, Texas, Virginia, Wyoming
5-34 per cent	14	Alabama, Arizona, Arkansas, Georgia, Idaho, Kentucky, Mississippi, New Mexico, North Carolina, North Dakota, South Carolina, South Dakota, Vermont, West Virginia

cent (Table XII). The disparity is undoubtedly explained by the difference in life expectancy and opportunities for comprehensive medical care. *Central and Midwestern states* (Ohio, West Virginia, Illinois, Missouri, Minnesota, Kansas, Michigan, and North Dakota).

The correlation between short life expectancy and a diminished incidence of cancer of the stomach is strikingly demonstrated in this group of states. In West Virginia, where 16.1 per cent of the population have passed the age of fifty, the mortality was 14.9 compared to 25.1 in North Dakota, where 19 per cent of the population survived the fifth decade. The rural population of these states was, respectively 71.9 and 79.4 per cent. The higher incidence in North Dakota was probably bolstered by its larger proportion of hospital beds, one to every 253 persons, compared to one in every 359 in West Virginia. On the other hand, the latter had a somewhat larger ratio of physicians.

A similar relationship emerges when predominantly rural North Dakota is compared to states with a large urban population viz. Illinois (73.6%) and Michigan (65.7%). With 22.1 per cent of its population in and past the sixth decade of life Illinois had a death rate of 24.1 per 100,000 from gastric cancer while Michigan, with 19.8 per cent of its residents over 50 years of age, had a mortality of 21.6. In spite of the varying ratios of urban to rural population, all of these states had important factors in common viz. a high degree of longevity, a superior economic and educational status

and easy access to first class medical facilities. Illinois and Michigan have seven medical schools between them and respectively provide a hospital bed for every 277 and 238 persons.

Missouri and Minnesota with almost equally divided urban and rural populations, complete the comparison. With 23.5 per cent of its population over 50 years of age the former had a death rate of 20.3 per 100,000 and the latter with an over 30.1 population of 21.0 per cent, a mortality of 29.6. The seeming disproportion in favor of Minnesota may be accounted for by its more favorable ratio of physicians and hospital beds, plus the unusual concentration of patients with gastro-intestinal cancer at the Mayo Clinic.

Far Western states (Wyoming, Washington and California)

Again in this section the distribution of urban and rural communities afforded no key to the incidence of gastric cancer. Wyoming, with a rural population of 62.7 per cent, had a death rate of 18.2 compared to 23.9 for California, with a rural population of 29 per cent, and a high of 28.2 for Washington, with a 46.9 per cent rural population.

The distribution of medical facilities was also inconclusive. Washington, with no medical colleges at the time of these statistics, one hospital bed to every 232 persons, and one physician to every 789 had a higher recorded incidence than California, with four medical schools, a hospital bed for every 187 residents and a physician for every 580 persons. Although Wyoming apparently provides ample hospitalization (a bed to every

TABLE X.—RATIO OF GENERAL HOSPITAL BEDS TO POPULATION IN THE UNITED STATES, 1940

Ratio of hospital beds to population	Number of states	States
1:50-1:40 persons	16	Arizona, California, Colorado, Delaware, Maryland, Massachusetts, Michigan, Montana, Nevada, New Hampshire, New Mexico, New York, Rhode Island, Vermont, Washington, Wyoming
1:30-1:49 persons	12	Connecticut, Florida, Idaho, Illinois, Kansas, Louisiana, Maine, Minnesota, Missouri, Nebraska, New Jersey, North Dakota, Oregon, Pennsylvania, South Dakota, Utah, Virginia, Wisconsin
1:20-1:49 persons	9	Alabama, Indiana, Iowa, North Carolina, Ohio, Oklahoma, South Carolina, Texas, West Virginia
1:10 persons or more	5	Arkansas, Georgia, Kentucky, Mississippi, Tennessee

TABLE XI.—RATIO OF PHYSICIANS TO POPULATION IN THE UNITED STATES 1940

Ratio of physicians to population	Number of states	States
1,400-500 persons	4	California, Colorado, Massachusetts, New York.
500-100 persons	3	Connecticut, Delaware, Illinois, Maryland, Minnesota, Missouri, Nevada, New Hampshire, New Jersey, Ohio, Oregon, Pennsylvania, Rhode Island, Vermont, Washington.
300-100 persons	5	Arizona, Florida, Indiana, Iowa, Kansas, Louisiana, Maine, Michigan, Nebraska, Oklahoma, Texas, Utah, Virginia, Wisconsin, Wyoming.
11,000 persons or more	14	Alabama, Arkansas, Georgia, Idaho, Kentucky, Mississippi, Montana, New Mexico, North Carolina, North Dakota, South Carolina, South Dakota, Tennessee, West Virginia.

193 people) it has a low rate of physicians—one to 915

Longevity figures provide better correlation. In Washington where the fatalities from gastric cancer were highest, 24.9 per cent of the population survived the half century mark. California was second both in mortality and length of life. With the lowest incidence Wyoming also had the shortest life span with only 17.9 per cent of its population past the age of 50

TABLE XII.—POPULATION FACTORS AND FACILITIES FOR MEDICAL CARE IN RELATION TO DEATH RATE FROM GASTRIC CANCER.

United States and Twenty Selected States, 1940

State	Death rate per 100,000	Ratio population.		Per cent of urban population
		Physicians	Hospital beds	
United States	19.8			
Massachusetts	16.1	547	98	89.4
Vermont		687	37	34.3
New York	3.6	497	3	8.3
Pennsylvania	1.3	71	8	66.5
Ohio	4	74	153	66.8
West Virginia	4.0	207	150	18
Illinois	24	648	277	73.6
Missouri	20.5	714	3.6	83.8
North Dakota	5.2	50	5	6
Minnesota	19.6	797	21	49.6
Michigan	6	870	38	65.7
Kansas	8.9	870	277	41.0
California	13.0	1,380	87	7.10
Washington	18	1,786	3	53
Wyoming	6	105	93	37.3
Texas	11.5	1,030	4.5	43.4
Georgia	9.9	11,106	483	34.4
Mississippi		12,450	600	9.8
Alabama	9.7	11,364	41	30
Louisiana	14	950	273	41.5

Southern and Southwestern states (Georgia, Mississippi, Alabama, Louisiana, and Texas)

The extremely low recorded death rate for gastric cancer in these states (9.7 per 100,000 in Alabama, 9.9 in Georgia, 11.5 in Texas, 12.0 in Mississippi, and 15.4 in Louisiana) is a corollary of short life expectancy, insufficient public health education, and proportionately few medical institutions. This is a predominantly rural region with a large proportion of negroes, the rural population ranges from 54.6 per cent in Texas to a high of 80.2 per cent in Mississippi. Medical facilities are not as universally available as in other sections; there is only one physician to more than 1,000 persons in Georgia, Alabama, and Mississippi, and only a slightly better ratio in Texas and Louisiana. Hospital beds are also inadequate for the most part; only Louisiana provides a bed for fewer than 300 persons, while Georgia and Mississippi are in the lowest category, with one bed to 483 and 649 persons, respectively. Mississippi is without a medical school.

The 1940 longevity for this section was considerably below the average of the country as a whole. Whereas 20.4 per cent of the general population lived more than five decades, the corresponding percentage for Alabama was 14.9, Mississippi 15.2, Louisiana and Georgia 15.4, and Texas, 16.6. These figures run fairly parallel to the low mortality rates for gastric cancer and the lower educational and public health level of the states in question.

It is our belief that the apparent gross variations in the incidence of gastric cancer in different parts of this country—and indeed throughout the world—do not reflect a genuine difference in susceptibility as much as variations in the general sociological plane. With the establishment of adequate medical facilities and education of the public in their early use, the disease is more frequently diagnosed and a higher morbidity rate recorded. At a common level of longevity, economic security, and public health education and opportunity, it is probable that the incidence of gastric cancer would be approximately the same the world over.

TABLE XIII.—DEATHS FROM CANCER OF THE GASTROINTESTINAL TRACT

Location	United States		England and Wales		Australia		Germany	
	Number	Per cent	Number	Per cent	Number	Per cent	Number	Per cent

SOCIOLOGICAL FACTORS

In contrast to the apparent preponderance of gastric carcinoma in regions on a high plane of industrial and medical development, there is evidence that the disease is actually more common at the lower social levels (11 33 54 63). At the ages 35 and 36 standardized mortality ratios for cancer of the stomach and esophagus in England and Wales (1930 to 1932) showed an increase in incidence with each descent of the social scale. The rate rose from 114 for the professional and independent class to more than double (248) for unskilled labor.

Bavarian statistics tell a similar story (7). Carcinoma of the stomach accounted for 70.6 per cent of all cases of malignant tumors among agricultural workers and for 66 per cent among artisans. As the social and economic level rose, the proportion lessened, reaching 39 per cent for brewers and publicans, 29.6 per cent for merchants, and a low of 24.2 per cent for clerics.

Other German observers (Mahlisch) cite a rate of from 30 to 36 per cent for people who "live well" as compared to 54 per cent for those in less fortunate circumstances. According to their experience, gastric cancer is relatively rare among the well to do.

In contrast to those observations are insurance reports (Hoffman, 25) showing a distinctly higher mortality from neoplasms of the stomach among

ordinary policyholders than among the poorer industrial risks. On the basis of gastric analysis, Lintott found no constitutional difference between the stomachs of the rich and the poor.

The paucity of authoritative data on this aspect of the incidence of gastric carcinoma underlines the need for more uniform and comprehensive records. In addition to age, sex, and race, occupation might profitably be included as a regular feature of case histories.

RATIO OF GASTRIC CANCER TO OTHER NEOPLASMS OF THE DIGESTIVE TRACT

Of all the organs of digestion, the stomach is most vulnerable to carcinomatous invasion (Table XIII). The intestines hold second place, although the duodenum is rarely attacked.

In 1940 in the United States, malignant tumors of the digestive tract and peritoneum represented 53.2 per cent of the total cancer deaths. Gastric cancer predominated in this group (36.5%) with carcinoma of the intestines second (24.5%). New growths of the liver and biliary passages (13.4%) and of the rectum and anus (12.2%) were next in importance.

Great Britain showed approximately the same distribution, with the stomach and the duodenum the primary sites in 36.4 per cent of the fatal neoplasms of the digestive organs and peritoneum. Cancer of the intestines, other than the duodenum,

TABLE XIV — DISTRIBUTION OF CANCER OF THE GASTROINTESTINAL TRACT
Memorial Hospital, New York New York.

Location	1944		1945		1946	
	Number	Per cent	Number	Per cent	Number	Per cent
Total	169	100	45	100	804	100
Esophagus	15		28		9	1.1
Diaphragm, peritoneum, mesentery and associated abdominal cancer						
Stomach	1	24.6	5		0	2.8
Liver, gall bladder and ducts	9	0			99	9.6
Pancreas	7	5	6	3	9	7
Spleen						
Small Intestines						
Large Intestines, right	24	5	25	7.8	40	7.9
Large Intestines, left	40	5	31	7.8	40	7.9
Large Intestines, generalized						
Rectum and anus	4				1	0.6
	102	4.7	66	30	25	44.8

ranked second (27.1%) with rectal carcinoma third (15.7%). New cancers of the liver and bile passages played a less important role than in the United States, causing only 7.6 per cent of the mortality of the gastrointestinal tract.

In Germany the stomach and duodenum were the seat of an exceptionally large proportion (55.3%) of the fatal neoplasms of the digestive tract. Cancer of the liver and gall bladder caused 16.0 per cent of the deaths in this category, cancer of the rectum 8.3 per cent.

Australian figures approached the American and British, with gastric and duodenal carcinoma causing 42.8 per cent of the deaths attributable to malignant tumors of the digestive organs, and cancer of the intestines 25.8 per cent. The mortality from neoplasms of the liver and biliary passages was low (7.6%) as in Great Britain.

For the incidence of cancer of the gastrointestinal tract in morbidity statistics, patients treated at the Memorial Hospital for selected years are presented in Table XIV. The distribution according to the site of the cancer may be determined to some extent by the number of beds assigned to the different services and the difference in length of time required for hospitalization.

INCIDENCE OF GASTRIC CARCINOMA IN RELATION TO OTHER GASTROINTESTINAL DISEASES

Little has been published on the frequency of gastric neoplasms in comparison to other diseases

of the digestive tract. In one series of 3,000 patients presenting gastrointestinal symptoms, 15 per cent had organic disease of the stomach or duodenum, distributed as follows: 9.8 per cent, duodenal ulcer; 1.6 per cent, gastric ulcer; and 3.1 per cent, gastric carcinoma, less than one per cent comprised benign lesions (10). In other words, many of all organic lesions found.

At the Toronto General Hospital, 1,724 admissions for chronic gastrointestinal disease yielded 227 cases (13.2%) of gastric cancer (18). This diagnosis was established in 8.7 per cent of the report as a group of 1,869 private surgical cases. In the hospital series, chronic gall bladder disease was 2.6 times as prevalent as carcinoma of the stomach and duodenal ulcer 3.0 times as common. Gastric cancer revealed approximately the same relationship except for a higher proportion of chronic gall bladder disease (4.4 to 1).

Still another report on 1,000 cases (44) disclosed a comparable distribution of gastric ulcer (3.1%), duodenal ulcer (17.1%) and gastric cancer (7.1%).

SUMMARY

1. Cancer is not a reportable disease with the result that no all inclusive figures on its occurrence are available.

2. The reported incidence of gastric cancer throughout the world with but few exceptions varies directly with the economic status, educational and medical facilities, and life expectancy of the community or country.

3. Fatalities from cancer of the stomach reach their highest level between the sixty fifth and seventieth years although 4.7 per cent of the deaths took place between the thirtieth and forty fourth.

4. A most striking rise in the crude death rate from gastric cancer among negroes was noted.

5. The disease was shown to be slightly more prevalent among non-Jews than Jews in European cities.

6. Of all the organs of digestion the stomach is the most vulnerable to the occurrence of cancer.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

EYE

Experimental Study and Comparison with Ocular Effects on Freezing. W. MORTON GRANT. *Arch. Ophth., Chic.* 1947 35 762.

The author states that it is the chemical not the refrigerant, properties of liquid sulfur dioxide which are primarily responsible for damage to the cornea. Sulfur dioxide exerts its toxicity principally in the form of sulfurous acid. Sulfur dioxide produces an acid burn in the eye.

Freezing of the anterior part of the living eye of the rabbit for several seconds resulted in a mild and transient disturbance. Freezing for 30 to 90 seconds caused loss of the endothelium with consequent edema of the stroma and epithelium, changes unlike those produced in accidental injury of the eye with liquid sulfur dioxide.

Sulfur dioxide exerts its toxic effect principally in the form of sulfurous acid. No significant production of sulfonic acid was detected.

The epithelium and stroma of the cornea have a relatively high permeability to sulfur dioxide. This is related to the lipid solubility of sulfur dioxide.

Contrary to previous opinion, production of injury by liquid sulfur dioxide is not attributable to freezing or to the formation of sulfonic acid, but to its ready penetration of the corneal epithelium in high concentrations and its action principally as sulfurous acid in denaturing corneal proteins including enzymes.

JOSHUA ZUCKERMAN M.D.

Surgical Correction of Superior Oblique. W. P. McGUIRE. *Am. J. Ophth.* 1948 31 65.

Paralysis of the superior oblique muscle is the most frequent individual extraocular muscle condition next to paralysis of the external rectus muscle. Complete paralysis of the superior oblique is rare under action or paresis is common.

It is characterized by (1) habitual torticollis with the head most frequently tilted toward the side opposite to that of the paretic muscle, (2) vertical diplopia which increases when the paretic eye is carried downward and inward (3) hypertropia which increases when the eye is carried into the field of action of the paretic superior oblique muscle. Nausea and vomiting may occur.

Before 1934, at which time Wheeler described his operation, the condition was corrected by attacking the yoke or the direct antagonistic muscle by tenotomy of the inferior oblique of the same eye, and by (the less popular) recession of the superior rectus of the same eye. In a few cases the homolateral inferior rectus muscle was advanced.

The most logical procedure for the relief of the symptoms is operation on the paretic muscle itself—resection of the tendon of the superior oblique. There are no definite rules as to the amount of tendon to be resected but immediate overcorrection is desirable. If this procedure fails then other methods may be tried. However secondary procedures are seldom necessary.

Intraocular Foreign Bodies in Soldiers. HELENER CAMPBELL WILDER. *Am. J. Ophth.* 1948 31 57.

Foreign bodies of many types were found in eyes of soldiers following injury during training and combat. Of these, 37 per cent were magnetic, 62 per cent were nonmagnetic, and 1 per cent were mixed.

It is concluded that nonmagnetic intraocular foreign bodies predominate in military injuries. However many injured eyes do not reach the laboratory because a foreign body may have been successfully extracted by a magnet and even in enucleated eyes nonmagnetic foreign bodies are often secondary to ferrous missiles which may have been extracted.

Associated infections and reactions often occur. Infection was generally due to the staphylococcus resulting in purulent panophthalmitis. Reaction associated with siderosis bulbi was mild. Sympathetic ophthalmia developed in 4 cases of retained nonmagnetic foreign bodies and in one case of ferrous foreign body. Glaucoma occasionally occurred in association with siderosis bulbi and in cases in which the foreign body was lodged in the anterior chamber. However, glaucoma was a comparatively rare end result and phthisis bulbi a common end result. Granuloma surrounded any kind of foreign body.

JOSHUA ZUCKERMAN M.D.

Ocular Injury Due to Sulfur Dioxide. I Report of 4 Cases. W. MORTON GRANT. *Arch. Ophth., Chic.* 1947 35 755.

The author discusses ocular injury caused by sulfur dioxide. Sulfur dioxide in high concentration in the form of the liquefied gas is commonly used in domestic refrigerators. It is an occasional cause of serious injury to the eye.

Sulfur dioxide may cause immediate alterations in the cornea, due (as in acid burns) to opacification of the corneal epithelium which remains adherent to the stroma. At first damage to the corneal nerves with resultant anesthesia causes only slight discomfort. Several hours, or days, later the vision becomes blurred, the eyelids swollen, and the conjunctival vessels thrombosed. Still later when the opaque corneal epithelium is lost and better vision occurs evidences of deeper injury—edema of the stroma.

opacity of the corneal nerves, and a grayness and irregularity of the endothelium—become visible. Such changes resemble those produced by burns with alkalis. Infiltrates in the stroma, vascularization of the interstitial tissue, and moderate thickening of the stroma are common.

Corneal scarring, conjunctival overgrowth of the cornea, and the formation of symblepharoid are the most frequent complications. Iritis or glaucoma did not occur.

It is emphasized that, contrary to general belief sulfur dioxide is not innocuous. In 4 reported cases, spraying of liquid sulfur dioxide and oil into both eyes resulted in immediate damage to the corneal epithelium as in acid burns, and to the underlying stroma and the endothelium as in alkali burns.

In mild cases complete recovery occurs in severe cases dense opacification follows infiltration in the cornea and vascularization of the interstitial tissue.

JOSIEA ZUCKERMAN, M.D.

Data on the Occurrence of Calcification in the Eye
TISSENA. MAGDA RADNOT *Brit. J. Ophth.* 1945, 38: 47

The author collected 12 cases of calcareous degeneration of the cornea. In 2 of the patients, lime was deposited in the cornea in an irregular form and in 10 as a zonular opacity. In the cases of zonular opacity calcareous deposits were found in the region of Bowman's membrane and in the form of discs in layers under it. In most cases hyaline granules could also be found beside the calcareous lamellae. In the advanced cases the calcification was extensive and Bowman's membrane was lacking.

On the basis of these 12 cases the author describes the concomitant occurrence of lime in other eye tissue. Lime was frequently found in the choroid as bone lamellae. Calcareous degeneration was observed in lenses. Deposits of lime in a degenerate retina or in a chorioretinal scar were rare.

Corneal and Conjunctival Pigmentation among Workers Engaged in the Manufacture of Hydroquinones. BARKS ANDERSON *Arch. Ophth.* Chic. 1947 35: 2

The author presents a survey on the incidence and severity of corneal and conjunctival pigmentation in workers engaged in the manufacture of hydroquinone. From these patients the author has reconstructed the sequence of events in this condition. After about 3 years of exposure to hydroquinone vapor a brownish tinge against the normally white sclera in the interpalpebral portion is noted. The conjunctiva in these areas appears slightly dried and to have a white frothy foamlike deposit attached to it. The deeper portions of the conjunctiva acquire a light-brownish sepioid stain. The cornea remains clear.

After 2 or 3 more years the conjunctiva appears thicker and drier and small discrete dark brown to yellowish granules or globular precipitates are ob-

served in the deeper structures. Some migration of pigment from the limbus into the cornea can usually be observed at this time.

After a total of 5 or more years of exposure, the following picture is frequently found. Involvement is always limited to the interpalpebral zone of both the conjunctiva and the cornea. In the superficial layers of the conjunctiva fine glasslike spherules are found along the course of the superficial veins. Fine discrete brownish granules in sizes up to one millimeter are noted and extend down as deep as the basal epithelial cells where the larger granules are found. In the cornea just under or above Bowman's membrane are many fine grayish translucent and highly refractive dots. Vertical wrinkles are frequently found in Descemet's membrane. Two types of pigmentation are noted: (1) many fine dark brown to yellowish granules, and (2) a greenish-yellow homogenous stain permeating the entire anterior layers of the cornea. Small scarred areas are seen lying beneath the epithelium. The cornea becomes roughened though it does not stain with fluorescein. The terminal nerve filaments appear enlarged and may account for the frequent hyperthemia.

It was found that the age of the individual and length of employment, correlated with the degree of exposure, was the most constant factor in determining the degree of injury. The prognosis is not good in that, while conjunctival and corneal staining tend to disappear after a time, there is permanent scarring of the cornea and damage to vision. There seems to be no treatment other than prevention.

ROGER H. JOHNSON, M.D.

Treatment of Perforated Corneal Ulcer by Antoplastic Scleral Transplantation. SVEN LARSSON. *Brit. J. Ophth.* 1945, 38: 54.

Following the transcranial removal of a retrolental hemangioma in a 7 year old girl a lagophthalmic corneal ulcer developed into a descemetocoele. Four attempts to close this lesion with a conjunctival flap were of no avail. Since the lesion was off center an opaque transplant could be used. Therefore, a 2.5 millimeter scleral disc was removed from just below the external rectus muscle of the involved eye. The corneal defect was cleaned and enlarged and the scleral disc was fitted into the hole. A conjunctival flap was thrown over it. The disc healed in place and the final vision was comparatively good.

ROGER H. JOHNSON, M.D.

Solar Retinitis. EDWARD ROSEN *Brit. J. Ophth.* 1948, 31: 3.

Various cases of solar retinitis as presented by other authors were reviewed. These patients had had a visual loss following looking into the sun or at a welding flash.

The author describes a patient who following prolonged gazing directly into the sun, had had a considerable loss of vision in each eye. Fundus examination 6 weeks later showed each macula to have a peculiar greenish color with a pigment halo just

around the foveal reflex. Anterior to the foveal depression was a small, whitish-gray fluffy area. The picture was bilateral. The whitish areas disappeared in 10 days and the maculae became darkened. Five weeks later a definite hole had appeared in each macula. These holes were surrounded by a pigmented ring.

The author reported 23 cases with a macular hole or holes. All these patients had reduced vision and usually had a history of watching the sun directly but occasionally of watching reflected sun. He believes medical education for the prevention of these holes is important.

ROGER H. JOHNSON, M.D.

Surgical Treatment of Syphilitic Primary Atrophy of the Optic Nerves (Syphilitic Optochiasmatic Arachnoiditis): A Clinical-anatomic Study. WATKINS L. BRUNZSCH. *Arch. Ophth.*, Chic., 1947, 38, 735.

The author discusses the propriety of surgical intervention in patients with primary syphilitic atrophy of the optic nerves due to syphilitic optochiasmatic arachnoiditis. The discussion is based on a histologic study of 12 cases.

Four patients presented no arachnoidal adhesions at all. In 2 cases some slight arachnoidal thickening was observed which was considered normal and 6 cases presented definite syphilitic arachnoiditis in the optochiasmatic region. Although grossly these 6 cases presented pronounced thickening of the arachnoid embracing the optic nerves the chiasm and at times the third and other cranial nerves. Microscopic examination revealed that the thickened arachnoid passed harmlessly over the optic nerves and chiasm without pressure on the optic nerves.

It is pointed out that primary syphilitic atrophy of the optic nerve is the result of an inflammatory process in the intracranial part of the optic nerve and chiasm which originates in a basilar syphilitic meningitis. Only in some cases is an optochiasmatic arachnoiditis produced.

It is concluded that surgical removal of the arachnoidal adhesions is of little if any benefit because the inflammatory process within the optic nerves and chiasm remains unaltered by the operative procedure.

The most efficacious treatment for this condition is malarial therapy aided by a course of concomitant and subsequent injections of penicillin—5,000,000 units in each course. JOSHUA ZUCKERMAN, M.D.

EAR

Further Observations on Temporary Deafness following Exposure to Gunfire. G. REID, *J. Laryngol.*, Lond., 1946, 61, 609.

This report is a continuation of an earlier article on the same subject, but gives the results in greater detail than the first one.

It is stated that the experiments were carried out with a blank rifle cartridge fired a certain distance

from the patient's ear and that about 15 minutes after the test an audiogram was taken. The author gave the distances of the muzzle of the rifle from the subject and also the possible variables that might have been present in production of the noise.

It was found that the average hearing loss for each subject usually increased steadily as each round was fired until with some subjects, further shots at the same intervals caused only slight further increase in deafness. The author showed that the noise usually effected one frequency and as further rounds were fired to the same subject other frequencies above and below were affected.

It was proved that some men are much more sensitive to the noise than others and that it is not possible to determine which subject is sensitive and which is not. There was no evidence that the size or shape of the external auditory canal or the position of the pinna relative to the head is of any importance in causing the variation of sensitivity from one subject to the other. One possibility is the presence or absence of a plug of cerumen which, when present, may cause less sensitivity.

It is shown in the discussion and by experimental proof that the sensitivity of a certain subject may vary according to whether or not he has had previous exposure to loud sound. The author gives briefly the possible reasons why the same individual may have less sensitivity in sound after repeated exposures.

The author shows that very rapid fire causes less deafness than a slow rate of fire and gives possible explanations for this. He shows that a moderately rapid rate of fire affects the frequencies of 4096 and above while the slow rate of fire seems to produce its main effect in the frequency range between 2048 and 4096 complete vibrations per second.

All gunfire regardless of the type, affects mainly the high tones and the results depend upon the individual rather than the gun and there is no characteristic audiogram that can tell the type of noise which produces the deafness.

The time of recovery is shortest in the lowest frequency and longest in the highest frequencies. When the deafness is severe there is usually a lag of several hours before recovery begins in the upper frequency and occasionally the deafness increases after exposure before recovery begins. After recovery sets in, its rate follows a roughly exponential curve. The last frequency to recover was usually either 9747 or between 4096 and 5993 c.p.s. Usually the patients with audiograms showing peak losses between 30 and 40 decibels recovered in 24 to 48 hours and those with losses of 30 decibels recovered in a few hours and sometimes within 1 hour. In the review of the recovery curves the impression was sometimes obtained that certain frequencies passed through a phase of hypersensitivity before settling down to the pre-exposure level.

The study of the recovery curve leads to the consideration of the mode of onset of permanent deafness. In the cases presented no serious permanent loss of hearing was produced by the exposure to the

opacity of the corneal nerves and a grayness and irregularity of the endothelium—become visible. Such changes resemble those produced by burns with alkalis. Infiltrates in the stroma, vascularization of the interstitial tissue, and moderate thickening of the stroma are common.

Corneal scarring, conjunctival overgrowth of the cornea, and the formation of symblepharon are the most frequent complications. Intus or glaucoma did not occur.

It is emphasized that, contrary to general belief sulfur dioxide is not innocuous. In 4 reported cases spraying of liquid sulfur dioxide and oil into both eyes resulted in immediate damage to the corneal epithelium, as in acid burns and to the underlying stroma and the endothelium as in alkali burns.

In mild cases complete recovery occurs; in severe cases dense opacification follows infiltration in the cornea and vascularization of the interstitial tissue.

The most efficacious treatment for this condition is malarial therapy aided by a course of concomitant and subsequent injections of penicillin—5,000,000 units in each course.

JOSEPH ZUCKERMAN, M.D.

EAR

Further Observations on Temporary Deafness following Exposure to Gunfire. G. REID, *J. Laryngol.* 1946, 61 609.

This report is a continuation of an earlier article on the same subject, but gives the results in greater detail than the first one.

It is stated that the experiments were carried out with a blank rifle cartridge fired a certain distance

from the patient's ear and that about 15 minutes after the test an audiogram was taken. The author gave the distances of the muzzle of the rifle from the subject and also the possible variables that might have been present in production of the noise.

It was found that the average hearing loss for each subject usually increased steadily as each round was fired until, with some subjects, further shots at the same intervals caused only slight further increase in deafness. The author showed that the noise usually effected one frequency and as further rounds were fired to the same subject other frequencies above and below were affected.

It was proved that some men are much more sensitive to the noise than others and that it is not possible to determine which subject is sensitive and which is not. There was no evidence that the size or shape of the external auditory canal or the position of the pinna relative to the head is of any importance in causing the variation of sensitivity from one subject to the other. One possibility is the presence or absence of a plug of cerumen which, when present, may cause less sensitivity.

It is shown in the discussion and by experimental proof that the sensitivity of a certain subject may vary according to whether or not he has had previous exposure to loud sound. The author gives briefly the possible reasons why the same individual may have less sensitivity to sound after repeated exposures.

The author shows that very rapid fire causes less deafness than a slow rate of fire and gives possible explanations for this. He shows that a moderately rapid rate of fire affects the frequencies of 4006 and above while the slow rate of fire seems to produce its main effect in the frequency range between 2048 and 4006 complete vibrations per second.

All gunfire, regardless of the type, affects mainly the high tones and the results depend upon the individual rather than the gun and there is no characteristic audiogram that can tell the type of noise which produces the deafness.

The time of recovery is shortest in the lowest frequency and longest in the highest frequencies. When the deafness is severe there is usually a lag of several hours before recovery begins in the upper frequency and occasionally the deafness increases after exposure before recovery begins. After recovery sets in its rate follows a roughly exponential curve. The last frequency to recover was usually either 9747 or between 4006 and 5793 c.p.s. Usually the patients with audiograms showing peak losses between 30 and 40 decibels recovered in 24 to 48 hours and those with losses of 20 decibels recovered in a few hours and sometimes within 1 hour. In the review of the recovery curves the impression was sometimes obtained that certain frequencies passed through a phase of hypersensitivity before settling down to the pre-exposure level.

The study of the recovery curve leads to the consideration of the mode of onset of permanent deafness. In the cases presented no serious permanent loss of hearing was produced by the exposure to the

noise. One patient, however showed a very slow recovery and about 8 months after exposure considered that his hearing had not returned. This particular patient had been exposed to seven exposures of the same or less severity during 13 days prior to the last exposure to the noise which seemed to bring on some permanent deafness. This seems to show that it is possible that one extremely severe exposure may result in permanent damage if the patient had also been exposed to previous loud sounds from which, however he had recovered.

The author presented a number of charts, graphs, and records of the cases.

WILLIAM A. ARBROW, M.D.

Some Observations on Bone Conduction following the Fenestration Operation. R. R. WOOD. *J. Laryng. Otol.* 1943, 63, 21.

From the beginning otosclerosis appears to produce a middle ear deafness for low tones and a mixed type of deafness for high tones. As the disease progresses, bone conduction is reduced for low tones also and nerve deafness gradually develops.

It is generally thought that the fenestration operation for otosclerosis has no effect on nerve deafness as measured by bone conduction. Six audiograms are presented from patients who have had the fenestration operation. In 5, the fenestra was open and bone conduction as well as air conduction was improved. The opposite ear was masked with an electrical buzzer, mounted in the ear piece and giving an intensity level 75 decibels above threshold. The average increase for air conduction in the 518, 1024, and 2048 frequencies in the operated ears for all 5 cases was 29.4 decibels. The average increase in masked bone conduction for the same ears was 14.3 decibels. In the remaining case the fenestra had closed, and hearing by both air and bone conduction had returned to the preoperative level. The increase in bone conduction which accompanies the increase in air conduction in the successfully fenestrated ear is presented as a clinical observation for which the explanation has not yet been determined.

JOHN R. LEONARD, M.D.

The Present Status of the Diagnosis and Treatment of Endolymphatic Hydrops (Ménière's Disease). HENRY L. WILLIAMS. *A. n. Otol. Rhinol.*, 1947 50: 6-4.

It would seem that a more accurately descriptive term for Ménière's disease would be endolymphatic hydrops. The term "Ménière's disease" because it has been connected with so many different pathologic entities, has become confusing and should be dropped. Ménière did not clearly distinguish between the symptoms of endolymphatic hydrops and positional nystagmus with vertigo, and furnished as a probable pathologic basis for the condition the report of a case which did not meet the clinical criteria for the diagnosis which he had established. There is confusion in the minds of many commentators in Ménière's disease or syndrome between

the terms *dizziness* or "giddiness" and *vertigo*. Some of the confusion in regard to the proper differential diagnosis between Ménière's disease and other conditions in which either vertigo or dizziness is present would be corrected by a more careful use of terms. The first step in the treatment of vertigo or dizziness is the proper interpretation of the patient's complaints. Without this, effective treatment is not possible. The terms *dizziness* and *giddiness* should be restricted to an abnormal sensation of unsteadiness characterized by a feeling of movement within the head without the sensation of the external world or the patient himself being in motion. *Dizziness* or *giddiness* as a subjective sensation should not be confused on the other hand with the sensation of unsteadiness associated with ataxia. At times true vertigo and dizziness can coexist.

In caloric testing, a functional test of diagnostic significance in endolymphatic hydrops, one is measuring the absorptive properties of the surrounding tissues for either hot or cold as well as the functional condition of the labyrinth. Even though it has been pointed out that in the caloric test one can compare the reactivity of one ear with that of the other there still seem to be too many uncontrolled variables in a caloric test to allow general conclusions to be drawn. The directional preponderance test, while superior to previous methods of testing would not seem to add much to a diagnosis obtained by a well taken history and tests of cochlear function. Fortunately much of the confusion and controversy in regard to Ménière's disease has been dissipated by the discovery of the true pathologic picture in authenticated cases of this disorder. In all cases reported, gross dilatation of the endolymphatic system, affecting chiefly the scala media (ductus cochlearis B.N.A.) and the sacculus and utricle, is present. Minor degenerative changes are found in the organ of Corti and at times in the stria vascularis. In all cases reported inflammatory changes have been conspicuously absent. This pathologic picture at once disposes of a vast group of disorders that have been termed "pseudo-Ménière's disease" in which the underlying condition is usually inflammation.

In the course of treating a large number of patients who had endolymphatic hydrops the concept that the cause of this condition is a form of physical allergy was formed. Although many previous observers had suspected this relationship a search of the literature yielded only a little direct evidence in its favor. Acceptance of the hypothesis that there are two physiologic mechanisms with similar clinical expressions, immunologic allergy and physical or intrinsic allergy, resolves nearly all the difficulties that have prevented the general acceptance of endolymphatic hydrops as a type of allergy. The gist of the concept, that endolymphatic hydrops is a form of physical or intrinsic allergy is that the inherited tendency of the endothelial cells of certain capillary loops to react abnormally to the alarming stimuli of Selye is the anatomic and physiologic basis of the group of conditions known as physical allergies with

their disturbance of water and electrolyte metabolism consequent to altered permeability of the cell membranes of the affected cells

At the Mayo Clinic 55 patients whose condition was diagnosed as the physical allergy syndrome underwent the Atkinson test and subsequently were treated with either histamine or nicotinic acid with regard to the results shown by the test. The following conclusions were drawn from these tests: (1) there does not seem to be any agreement between the results of skin testing with histamine and the results of treatment (2) skin tests with histamine seem valueless both for diagnosis and as a guide to therapy (3) these findings do not bear out Atkinson's contention that vasospastic and vasodilating types of allergy exist, since the response of all types in the physical allergy syndrome was equally good to treatment with either histamine or nicotinic acid.

From a review of the literature it would appear that Atkinson's hypothesis that there are two types of persons who have endolymphatic hydrops has little if any clinical or laboratory evidence to support it. The author points out that any capillary vasodilator—probably by virtue of its action in opening up the capillary loops involved and sweeping out their contained local excess of histamine to be dilated and metabolized in the body generally—will produce results comparable to those of any other

recurring attacks of either sudden falling or vertigo and nystagmus with loss of hearing and usually tinnitus in the affected ear differentiation should be confined at least to those conditions which tend to produce recurring attacks of vertigo. Conditions inflammatory basis are (1) trauma of the head with injury to the labyrinth or its tracts (2) multiple sclerosis (disseminated sclerosis) (3) intermittent tubal occlusion (4) positional nystagmus (5) Bruns syndrome (6) carotid sinus syndrome and (7) toxic vertigo

Successful medical treatment of endolymphatic hydrops has always been based either on the hypothesis that permeability of the capillaries of the stria vascularis was increased or on the hypothesis that cording to the author this is essentially the same as considering endolymphatic hydrops to be a form of physical allergy

At the Mayo Clinic we have found that atropine in large doses (up to 1/175 grain [0.00037 gm]) will have a tendency to control the acute attack of endolymphatic hydrops as well as few minimis of 1/1,000 of epinephrine given intravenously. From the review of medical treatment it may be seen that those measures have proved effective which were directed toward correction of the electrolyte balance in the tissue fluids toward control of the fluid metabolism or toward stimulation of the autonomic nervous system and the production of vigorous vasodilation. This clinical evidence all points toward the conclusion that endolymphatic hydrops is an

allergic phenomenon usually of the physical or intrinsic type.

Surgical treatment of endolymphatic hydrops includes labyrinthotomy and intracranial division of the eighth nerve. At the Mayo Clinic patients who had endolymphatic hydrops have undergone destructive labyrinthotomy and have been completely relieved of vertigo. From the nature of the two procedures labyrinthotomy should be more free from untoward complications than intracranial division of the eighth nerve.

The author believes that in the United States as in England labyrinthotomy is destined to replace intracranial division. The fact that approximately a fifth of the patients on whom hemisection of the nerve is done subsequently have hearing on the side on which the operation was performed is surprising in view of the fact that the pathologic process appears to have its major expression in the ductus cochlearis and the normal expectation would be continued progress toward complete loss of hearing in the involved ear despite preservation of the cochlear nerve. In the selection of patients for surgical treatment, however those in whom the hearing in the involved ear is still useful and those in whom it can be demonstrated that restoration of hearing to useful levels can be obtained by medical means should not be considered candidates for surgical treatment.

Transmastoid Atticotomy in Chronic Tympanomastoid Suppuration. A. TOMARKIN, *Proc. R. Soc. M. Lond.* 1947 40: 761

Convinced that radical mastoidectomy is not the answer in chronic tympanomastoid suppuration the author evolved the transmastoid atticotomy technique after seeing a reference to the work of Thies on the transmastoid route.

Under general anesthesia and weak adrenaline solution infiltration, an incision (Fig. 1) is made by means of a fine knife and a slotted antral speculum. It starts at Sharpnell's membrane ascends to the outer attic wall to the midline of the roof of the external auditory canal, and turns downward and outward at the osseous and cartilaginous junction of the canal defining an elliptical flap which is easily elevated. The whole bone of the outer attic wall and the postsuperior wall is clearly exposed. Fine laryngeal excise semilunar pieces of bone starting at the tympanic ring. The chiseling is done gently and outward until the aditus, the short process of the incus, the perfect orientation almost at once (Fig. 2). The extent of the operation is determined by the findings if necessary the whole mastoid process can be explored. The anterior pouch of the attic should be left till the last, the incudomalleolar articulation being exposed in order to determine the fate of the incus whether it is to be preserved or not, and the subsequent amputation of the head of the malleus. After the necessary toilet the skin flap is rolled into place and lapped over the facial ridge to cover the raw edges

Fig 1

Fig. 1 (Tumarkin) Transmental atticotomy. The incision. Note the granulations on the posterosuperior quadrant of the tympanic ring. The tympanic membrane in that region has collapsed on to the inner tympanic wall.

Fig 2

Fig. 2. Transmental atticotomy. The bone incision completed. Showing incus, semicircular canal, facial nerve, and stapes. A comparatively limited excision of bone. The exposure can easily be extended forward, upward, or backward. The strip of bone overlying the head of the malleus would normally be removed so as to gain access to Prussak's pouch.

right up to the semicircular canal then reflex penicillin is squirted in to fix the flap. The first dressing is done about a week later and consists merely of syringing the selex out. Frequently small granulations form in the roof at the site of the original incision which should be gently snared off under cocaine anesthesia. Usually the cavity heals in from 4 to 6 weeks.

The rationale of atticotomy is that in chronic otorrhea the disease is in the middle ear attic, and aditus and in the great majority of cases, there are no outlying cells which are diseased or otherwise. The process is hypoplastic and is of the ivory or diploetic type. In from 60 to 80 per cent of the cases, it yields to simple hygiene of the outer ear from which it may be deduced that there is little or no involvement of the bone and the disease is confined to the accessible soft tissue adjacent to the tympanic ring. Next to this benign condition is the intermediate stage which consists of slight caries of the tympanic ring or of the ossicles and perhaps, some accumulation of granulation tissue and debris in the aditus or antrum hence the operation of choice will commence at the tympanic ring and may be followed up if the disease is extensive. Intracranial complications are rather rare at present and timely atticotomy will abolish such complications and, at least, preserve if not improve the hearing by saving the incus.

Criticism of this operation are as follows (1) it is performed in a dark pool of blood (2) there is insufficient room for manipulation (3) it endangers

vital structures such as the stapes, facial nerve dura and lateral sinus (4) one cannot with certainty reach the limits of the disease and (5) the operation is difficult and demands meticulous care and precision.

Among the advantages are (1) it takes only from 30 to 40 minutes (2) no sutures or ligatures are required (3) the postoperative care is simple (4) healing is rapid (5) the atticotomy flap does not encroach on the wax-bearing area so that crusts do not accumulate and (6) at times it is possible to preserve the incus.

From 50 consecutive patients, 43 replies to the questionnaires were received. Thirty-eight of the patients were completely healed and the 4 remaining had no gross purulent discharge. In certain cases, there was a substantial improvement in hearing, although in no case was hearing on the side operated upon as good as on the opposite side.

NOSE AND SINUSES

Osteomyelitis of the Basphenoid and Basocipit with Meningitis and Cranial Nerve Palsies as a Complication of Nasopharyngeal Packing for Control of Epistaxis: Report of a Case with Recovery. ARTHUR A. SPAR AND HENRY L. WILLIAMS. *Arch. Otolaryng. Chik.*, 1947 46: 473.

The authors report a case in which they call attention to the serious complications which may follow the use of nasopharyngeal packing for control

of epistaxis. In this instance abscess of the nasopharyngeal vault occurred and led to osteomyelitis of the basisphenoid and basiocciput meningitis and cranial nerve palsies. This is believed to be the first such case reported in which recovery occurred.

Sphenoid sinusitis almost always has been found to be the primary source of infection but the principles of extension of infection into the basisphenoid are equally applicable to infection originating on any surface of the body of the sphenoid. In this case the infection originated in the nasopharynx after trauma and stasis caused by prolonged nasopharyngeal packing. Trauma and infection of the nasopharyngeal mucosa probably led to thrombophlebitis of the vessels supplying this bone and osteomyelitis resulted.

The superior margin of the right choana well anterior to the adenoid region and inferior to the ostium of the sphenoid sinus was considered to have been the site of origin of the abscess. The size of the cavity in the basisphenoid was evidence that the overlying meninges must have been in close contact with the inflammatory process. Extension of the products of inflammation into the meninges in this region gave rise to the reactive meningitis. The possible presence of a nonunited metaphysis in the basisphenoid might have been an additional factor in the development of meningitis. Involvement of the medulla was assumed to have given rise to neurologic symptoms. Involvement of the masseter and pterygoid muscles was transient and was probably due to limitation of motion due to pain.

Though not apparent immediately in the critical period of the patient's illness a malignant lesion of the nasopharynx or of the sphenoid sinus with superimposed infection seemed a possible diagnosis so radium was used. Even though the lesion later proved to be nonmalignant the benefit of the use of radium in facilitating drainage became evident when the amount of pus coming from the nasopharynx increased noticeably within 24 hours after the use of radium.

Mucoceles of Frontal and Orbital Cells. H. BAUMWER AND L. SAVITT *Ann. Otol. Rhinol.* 1947 56 917

Mucoceles of the frontal and orbital ethmoid cells are not uncommon. The diagnosis is not difficult if the mucocele bulges into the nose or orbit. In those cases in which the extension is upward into the frontal sinus, the symptoms are not definite and even the roentgenogram often does not reveal the diagnosis.

Two cases are presented in which the operative findings were most likely that of ethmoid mucocele bulging into the frontal sinus. In the first case the posterior wall of the frontal sinus was extremely thin and bluish in color at time of surgery. After perforation of this plate a great amount of nonfetid pus escaped. This pus-containing pocket appeared to be a dilated ethmoid cell. The second patient was found during operation to have a frontal pyocoele. In addition, the floor of this dilated frontal sinus was entirely

membranous and thus membranous floor bulged into the sinus laterally. Further investigation proved this to be a cystlike sac filled with pus and lying between the frontal sinus mucosa and periorbit. In the first case a Lathrop-like sinus operation had been performed 16 years previously. Other investigators have noted that mucoceles may develop also following Gansen-Lynch and Killian operations.

Restoration of the Nose, Lip and Maxilla by Surgery and Prostheses. VARASTAD H. KAZANJIAN *Plast. Reconstr. Surg.* 1947 3 531

The combination of reparative surgery and maxillofacial prosthesis offers many advantages. Among other things the success of plastic surgery depends on restoration of contour particularly about the mouth and the maxilla. Without adequate support from within the mouth, satisfactory results in the contour of the lips and cheeks cannot be obtained. Prosthetic devices about the nose, orbit, and other parts of the face offer a more limited field generally when surgical methods are inadvisable or impractical.

A thorough and complete history of a patient in whom surgery and a prosthetic device were used to attain a satisfactory result, is presented. Numerous excellent pictures together with clear concise diagrams portray the various stages of surgical repair of the upper lip and a portion of the nose with the use of an intraoral nasopalatine prosthesis.

MOUTH

Condylar Growth and Mandibular Deformities. MITCHELL B. ENGEL AND ALLEN G. BRODIE *Surgery* 1947 22 976

This report is an analysis of 19 cases of arrested growth in the mandibular condyles and their subsequent deformities. It is the purpose of the study to emphasize the importance of the development and function of the jaw in the condylar area.

Mandibular growth results from an integration of activities in numerous areas and thus arrest of growth in the condyles results in pronounced mandibular deformities.

The authors give a very brief description of the development of the mandible and include several photomicrographs of the normal developments.

The condylar development is maintained in activity until about the twentieth year and this growth results in the normal forward and downward vector for the mandibular growth as well as the increased width of the jaw.

Disturbances in the growth of the mandible may occur as a result of mastoiditis or middle ear infection, hematogenous infections, infections in dental areas, or from injuries resulting in fractures or in disturbances of the bone-forming cartilage. Also generalized arthritis involving the temporomandibular joint may result in arrest of the development.

Also in animals, endocrine disturbances have been found to be a cause.

A series of 19 cases with history of involvement of the condyle was studied. The injury of the condyle was determined on the basis of history, x ray studies of the area (cephalometric, laminagraphic, and routine temporomandibular films) and analysis of joint function.

In several instances it was possible to follow the same individual serially over periods ranging from 1 to 15 years. In 8 cases the involvement was bilateral. Unfortunately however the histories were incomplete in many cases. Many cases gave a history of growth arrest that was early or congenital in origin. Others revealed an association of infections with subsequent ankylosis, but significant functional impairment was not always present. Orthodontic treatment was attempted in 8 cases, and 6 patients had arthroplasties.

For purposes of comparison the tracings of the mandibles of the same individual were superimposed upon the anterior portion and lower mandibular border as regions of relative stability since apposition and remodeling are minimal in those areas. The authors describe other measurements made of the jaws in their cases.

The clinical findings showed that when there was unilateral involvement the unaffected side usually appeared flat and underdeveloped, while the arrested side of the face gave the impression of fullness. The mandible was skewed toward the side of the affected condyle. There was generally notching of the lower border or the ramus-body junction. The patient was frequently unable to deviate the jaw toward the normal side.

With bilateral arrest of growth there was usually a symmetrical type of deformity resulting in a *V gelenck* with a very retruded mandible and the chin lying in the hyoid region. Lateral function was not always possible and the antegonial notching was present bilaterally.

The authors give a description of the roentgenological findings in the cases of unilateral and bilateral involvement. The authors also give a discussion on the disturbance of growth in these cases and state that sometimes growth may slowly begin again even though there appears to be a stoppage of growth, and therefore surgery is contraindicated unless it is definitely shown that all growth has been stopped by repeated examination of the patient. Surgery is not contraindicated if the cartilage has been prematurely ossified or so badly scarred as to preclude further growth. In older individuals the possibility of additional growth of the jaw does not constitute a problem.

Some authors believe that muscle imbalance is a major factor involved in producing the dysplasia. In the author's opinion the validity of such an assumption is difficult to sustain because of the following findings:

1. Resections of either the condyle or horizontally through the superior portion of the ramus for the

correction of mandibular prognathism in older people did not result in any significant changes in the form of body of the mandible over a period of years.

2. Injury to the condylar area in the cases reported here was not always associated with muscle disturbance as evidenced by the normal range of functional movements in some cases.

3. The authors have seen cases of functional limitation of obscure etiology in which there is almost complete inability to open the mouth, and in which the condylar area was undisturbed. In these individuals there was no deformity of the jaw.

4. This deformity does not occur in adult temporomandibular ankylosis.

The authors then briefly discuss the disturbances of function in the cases described because of the maldevelopment of the jaw and therefore poor function of the muscles of mastication.

The authors briefly discuss the treatment in these cases, stating that it is very difficult and that orthodontic treatment is capable only of modifying the alveolar process. The orthodontist can strive only for a correction of the occlusal relations of the teeth.

The efforts of the plastic surgeon together with those of the orthodontist are necessary to attain cosmetic improvement.

The authors include several photomicrographs of normal jaw development and photographs of several of their patients, as well as some roentgenograms. Some graphs are also included to show the relationship between normal and abnormal growth of the jaw.

PHARYNX

Ludwig's Angina—A Surgical Approach Based on Anatomical and Pathologic Criteria. *IVAR TORNBERG, Acta. Otol. Rhinol.* 1947 56: 937

Ludwig's angina begins as a cellulitis of the submandibular space. It attacks the fibrous tissue, fasciae and muscles but not the submandibular gland. It produces gangrene with a serosanguineous putrid infiltration, but usually there is little or no frank pus. Although many patients respond to chemotherapeutic and antibiotic drugs surgery is sometimes necessary. The goal of surgery is release of tension, and not a search for pus. The two structures chiefly responsible for this tension are the suprahyoid fascia and the mylohyoid muscle. Relief of tension is best achieved by dividing these structures at right angles to their fibers.

A transverse skin incision is made from a point one-half inch anterior to the angle of the mandible to a point beyond the midline. The underlying platysma muscle and suprahyoid fascia are cut transversely. The submental artery is ligated. The submaxillary gland is freed and retracted laterally. A grooved director is placed behind the mylohyoid muscle and its fibers are cut transversely. The mucous membrane of the floor of the mouth may be divided if tension is great. Section of the geniohyoid and digastric muscles and removal of the sub-

mandibular gland should be omitted. The same procedure may be necessary on the opposite side. Rubber drains are placed into the wound.

Asphyxiation is the most common cause of death. This may be due to obstruction of the air passages or to paralysis of the medullary respiratory center. Medullary paralysis can be caused by apnea as a result of persistent shallow rapid respiration or by hypersensitivity of the carotid sinus reflex due to the adjacent inflammatory process. Sudden death may be prevented if the following suggestions are heeded: (1) perform early tracheotomy when necessary (2) administer inhalation anesthesia only through a tracheotomy because introduction of a laryngoscope may induce fatal stimulation of the carotid sinus (3) manipulations in the regions of the carotid sinuses should be done only with the patient awake or under deep general anesthesia (4) local anesthesia is preferred.

JOHN R. LINDSAY, M.D.

Beta Hemolytic Streptococcus Parasitism in Infections of the Upper Respiratory Tract. NOAH FOX, *Arch. Otol. Rhin. 1947 46 703.*

The object of this study was to determine (1) the frequency of beta hemolytic streptococci in patients suffering from sore throat and (2) the response of these patients to local sulfathiazole therapy.

Although, generally speaking, these patients suffered from sore throat, they were readily divided into those who had acute exudative tonsillitis and pharyngitis and those who had nonexudative infection of the tonsils and the pharynx; the latter condition usually ushering in a general infection of the upper respiratory tract.

In this series of cases there seemed to be a definite relationship between streptococcal parasitism and the presence of tonsils or hyperplastic pharyngeal lymphoid elements. Patients with large masses of lymphoid tissue in the pharynx or with large tonsils definitely had greater bacterial counts of all organisms and were the sicker patients. Patients without tonsils and with little pharyngeal tissue were not so sick and were only infrequently harbors of beta hemolytic streptococci. Moreover their throats could be sterilized more rapidly.

Lymphoid tissue seems to supply the medium par excellence for growth of beta hemolytic streptococci, but the fact that these organisms have been recovered from the tonsils or from pharyngeal lymphoid tissue does not necessarily prove them to be the primary etiologic agent of disease. Beta hemolytic streptococci may be found in the throats of healthy persons. Hare found that on the average about 7 per cent of the normal population have these organisms in their throats.

One procedure available for the corroboration of a beta hemolytic streptococcus infection includes that of demonstrating antibodies during convalescence. This, however is too complicated for the ordinary office laboratory. Other procedures include determining the presence of an increase in the titer of anti streptolysin or antistreptolysin. Although the anti

streptolysin test is more highly specific, the antistreptolysin test is simple enough for routine clinical use. This test gives a positive reaction in about 80 per cent of cases of beta hemolytic streptococcus infection.

Throat culture studies were made of 400 patients suffering from sore throat. All had the sporadic types of sore throat seen in ordinary office practice. No epidemic conditions were included. In 64 patients unilateral or bilateral exudative tonsillitis or pharyngitis was present without any particular involvement of the pharyngeal mucosa except that covering lymphoid tissue. In 336 patients the soreness was due to a diffuse nonexudative inflammation of the pharyngeal lymphoid tissue and mucous membrane. The frequency with which beta hemolytic streptococci were isolated in the 64 cases of exudative tonsillitis and pharyngitis was 48 or 75 per cent, while the frequency in the 336 cases of nonexudative tonsillitis and pharyngitis was 24 or about 7 per cent.

Sulfathiazole is not as toxic as the other sulfonamide drugs and exerts an antibacterial effect on pneumococci and staphylococci, as well as on beta hemolytic streptococci. According to Pfeiffer and Holland, its bacteriostatic potency is twice that of other sulfonamide compounds.

In the procedure of treatment on which the present study was made, each of the two groups of patients classified on the basis of having exudative tonsillitis and nonexudative infections of the throat, respectively was divided into two numerically equal subgroups. In 32 of the patients who had exudative tonsillitis treatment consisted of having each chew a gum tablet containing 0.25 gm. of sulfathiazole for one hour repeating every other hour. The gum was chewed only during waking hours. Except for rest in bed no other local treatment was used. In the patients under this treatment any improvement noted must be credited to the local, rather than to the systemic, effect of the drug since previous experiments have shown that under similar conditions only a trace of sulfathiazole is found in the blood at the end of 12 hours. No other treatment was given except for the relief of pain.

The second subgroup of 32 patients with exudative tonsillitis was given a gargle consisting of warm saline solution. A glass of this solution was gargled every 2 hours. In addition these patients were placed on daily doses of 40 gr. (2.59 gm.) each of sodium salicylate and sodium bicarbonate. Patients with fever were put to bed.

The treatment instituted in the two numerically equal subgroups of the total of 336 patients with non-exudative tonsillitis was similar to that employed in the two subgroups of patients with exudative tonsillitis.

The average duration of clinical illness in the cases of exudative tonsillitis in which beta hemolytic streptococci were found was 3 days with sulfathiazole gum therapy while in those in which the salicylates were used the average duration was 3 days. In the cases of nonexudative tonsillitis in which sulfathia

Also in animals, endocrine disturbances have been found to be a cause.

A series of 19 cases with history of involvement of the condyle was studied. The injury of the condyle was determined on the basis of history, x-ray studies of the area (cephalometric, laminagraphic, and routine temporomandibular films) and analysis of joint function.

In several instances it was possible to follow the same individual serially over periods ranging from 1 to 15 years. In 8 cases the involvement was bilateral. Ludwig's Angina—A Surgical Approach Based on Anatomical and Pathologic Criteria. KURT TUCHMAN. *Ann. Otol. Rhinol.* 1947 56: 937

Ludwig's angina begins as a cellulitis of the submandibular space. It attacks the fibrous tissue fasciae and muscles but not the submandibular gland. It produces gangrene with a serosanguineous putrid infiltration, but usually there is little or no frank pus. Although many patients respond to chemotherapeutic and antibiotic drugs, surgery is sometimes necessary. The goal of surgery is release of tension, and not a search for pus. The two structures chiefly responsible for this tension are the suprahyoid fascia and the mylohyoid muscle. Relief of tension is best achieved by dividing these structures at right angles to their fibers.

A transverse skin incision is made from a point one-half inch anterior to the angle of the mandible to a point beyond the midline. The underlying platysma muscle and suprahyoid fascia are cut transversely. The submental artery is ligated. The submaxillary gland is freed and retracted laterally. A grooved director is placed behind the mylohyoid muscle and its fibers are cut transversely. The mucous membrane of the floor of the mouth may be divided if tension is great. Section of the geniohyoid and digastric muscles, and removal of the sub-

ment. In this manner the patients receive the quick action of Lugol's solution and the sustained action of propylthiouracil until the full control of hyperthyroidism is obtained. Iodine therapy therefore aids in the early clinical improvement and also reduces the vascularity of the thyroid gland for thyroidectomy. The slowing effect on the recovery due to the Lugol's solution is outweighed by the rapid clinical improvements. Patients with adenomatous goiter do not require iodine and a days of treatment are required for each percentage of elevation of the basal metabolic rate.

In the last 4 years 830 patients have been prepared for thyroidectomy with antithyroid drugs. Thiouracil was used 381 times, thiobarbital 28 and propylthiouracil 421 times. There was an operative mortality of 0.12 per cent as compared with 1.49 per cent prior to the preoperative use of these drugs. Two-stage operations have been reduced from 16 per cent to practically nil. As a result of experience proper preparation of the hyperthyroid patient with antithyroid drugs followed by thyroidectomy offers the best chance of restoration to health in the shortest period of time with minimal risk. The recurrence rate after 2 years in patients treated preoperatively with antithyroid drugs, is 2 per cent. 1 per cent required reoperation and 1 per cent obtained full control after a daily dose of Lugol's solution.

In the author's hands, thyroidectomy and the proper treatment resulted in cure in 95 per cent of his cases. The toxicity incidence of thiouracil is 9 per cent and that of propylthiouracil is 1.6 per cent.
 RICHARD J. BENNETT, JR., M.D.

The Clinical Significance of Examination of the Supraclavicular Lymph Nodes in Carcinoma
 (Ueber die klinische Bedeutung der Untersuchung der supraclavikulären Lymphknoten beim Krebs)
 ELMAR JAKOBSON *Acta chir scand* 1947 96 75

The frequency of occurrence of Virchow's gland in association with carcinoma of various organs was investigated. Supraclavicular metastases were noted on the left side in 129 of 914 cases of carcinoma originating in various organs (14.1 per cent). The incidence of supraclavicular metastases in carcinomas of the various organs was as follows: breast 21 per cent, prostate 18 per cent, liver and bile ducts 17 per cent, lung 16 per cent, stomach 14 per cent, ovary and uterus, 13 per cent, pancreas 12 per cent, intestines 8 per cent, and esophagus, 7 per cent. Since microscopic examination of the supraclavicular glands was done only in the doubtful cases (about 50 per cent) the figures given are based on macroscopic

diagnosis. The supraclavicular metastases varied in size from that of a pea to that of an orange. It is believed that metastases to the supraclavicular nodes is retrograde from the thoracic duct because of the proximity of the junction of the thoracic duct, the internal jugular vein and the efferent channels of the supraclavicular nodes. Variations in intrathoracic pressure and in venous pressure, particularly with forced expiration, could cause reflux of lymph laden with carcinoma cells into the efferent channels of the supraclavicular nodes.

In the entire series there were only 3 cases with bilateral supraclavicular metastases, the site of primary growth being the stomach, the lung and the liver in one instance each. Theories concerning the mode of spread to the right and left supraclavicular nodes are presented. Statistics of various investigators in the literature show that supraclavicular metastases occur much more frequently in association with carcinoma of the lung than with carcinoma of the stomach. Several authors attribute this to the fact that the lymph channels are much shorter in the former. Cases of prostatic carcinoma and of genital carcinoma in the female have been reported in which the first clinical symptom has been enlargement of the supraclavicular lymph nodes. A study of the age distribution of supraclavicular metastases showed the highest incidence to be in the younger age group.

The Mechanism of Phonation after Laryngectomy
 (Sobre el mecanismo de la fonación esofágica después de la laringectomía) ROBERTO C. FERRARI
Bol Acad argent cir 1947 31 693.

Esophageal phonation is today the only acceptable recourse to speech after laryngectomy. The efficiency of esophageal phonation depends upon three factors: (1) the degree of strength that is required; (2) the possibility of continuous speech for a certain length of time without fatigue and with enough intensity; and (3) the character of rhythm, tone and pitch resembling a laryngeal voice.

The mechanism of esophageal phonation depends upon two factors: (1) the intake of air into the esophagus and (2) the expulsion of this air to produce sound as it passes two mucosal folds which the author believes to be the main vibratory element (although other authors believe the cricopharyngeal muscle as most important in phonation).

With the use of the esophagoscope and roentgenogram, the author has observed the dilatation of the esophagus in its transverse diameter resembling a megacolon.

ARTHUR F. CROLLA, M.D.

zole gum was used, the average length of illness was 3 days and in those in which salicylates were used it was also 3 days.

NECK

Neoplastic Disease of the Thyroid Gland. JOHN C. McCLENNOCK and GUSTAVUS H. KLINCK, Jr. *West J Surg* 1948, 56: 52.

The authors review 331 cases now listed in the Cancer Registry of the American Association for the Study of Golter. The purpose of this Registry is to establish pathologic criteria for the recognition of malignant disease of the thyroid gland and also a generally acceptable classification.

The authors separate neoplasms of the thyroid gland into three major groups for the purpose of study. These include a group of definitely benign tumors a group of clearly malignant tumors, and (the largest group) a group containing all tumors in which the differential diagnosis between benignancy and malignancy is extremely difficult.

Neoplasms which are clearly malignant can easily be recognized by their departure from normal thyroid architecture which is characterized by a lack of differentiation and anaplasia by the presence of mitoses, and by evidence of local invasion or distant metastases. This group includes such types as large cell small cell, and epidermoid carcinomas, and according to many authors, the sarcomas. All cases of the large cell type of carcinoma or epidermoid carcinoma which were followed up for 3 years terminated fatally. Thirty five of these were in the Registry and all of the patients lived less than 15 months. In contrast, the life expectancy in small cell carcinoma is better as 3 patients lived 18 months and 1 died after 7 years from a cause other than the thyroid cancer. It seems likely that some of these may in reality be lymphoblastomas which respond to surgery and radiation therapy. The spindle form of large cell carcinoma caused early death.

Blood vessel invasion and capsule invasion are the most reliable criteria for the diagnosis of malignancy in the borderline groups. In 23 of 66 cases of adenocarcinoma, the diagnosis was based upon capsule invasion alone, with 2 deaths and two five year survivals to date. Blood vessel invasion was the sole diagnostic criterion in 7 cases. 4 of the patients are dead 2 dying of diseases other than thyroid cancer 3 survived 5 or more years. In 27 patients the diagnosis was established by the demonstration of both blood vessel and capsule invasion. Nine of these patients are dead and 9 have survived for 5 years. One patient is alive 27 years after the first diagnosis of cancer. In 9 cases the only criterion was invasion of the adjacent thyroid tissue. There have been 4 five-year survivals, but no deaths in this group.

In 36 of the papillary adenocarcinoma group of 60 cases, the diagnosis was based upon capsule invasion alone, with 5 deaths and 7 five-year survivals. Blood vessel invasion alone was the criterion in 7 cases, with 3 deaths and 3 five year survivals to date. Both

of these criteria were found in only 11 patients of whom 2 are dead and 2 have lived 5 or more years. Adjacent thyroid tissue was invaded in 6 cases with 1 death and 1 five-year survival to date. Capsule invasion alone is perhaps the most important diagnostic criterion in the papillary adenocarcinoma group.

The authors believe that several types of adenocarcinoma will ultimately be recognized. Among these are the so-called fetal type, the embryonal type, and the so-called Huerthle cell type.

ERNEST D. BLOOMENTHAL, M.D.

Thiouracil and Allied Drugs in Hyperthyroidism. EMER C. BARTLE. *N England J M* 1948, 38: 6.

As a result of the use of antithyroid substances in the treatment of hyperthyroidism there is a fall in the basal metabolic rate and a gradual amelioration of all hyperthyroid signs and symptoms except those of the eye. The antithyroid substance is active by preventing the synthesis of iodine to an active protein-bound hormone. Thiouracil was given in a daily dose of 600 mgm. Propylthiouracil, the drug now being used, is administered in a dosage of 500 mgm. a day. Thiobarbital had the highest incidence of complications, 18 per cent thiouracil, 9 per cent and propylthiouracil 1.6 per cent.

The use of antithyroid drugs as a means of treatment has certain specific disadvantages, and although the hyperthyroidism can be adequately controlled for a prolonged period it entails periodic observations or understanding of antithyroid therapy on the part of the physician or the patient.

Certain objections to this treatment include failure to bring about cure of the hyperthyroidism, the persistence of golter the inherent danger of not removing adenomatous golters, the possible reaction to the medication, and the possible development of serious histopathological change in the thyroid gland. The possibility of reaction to medication, although small is real, and past experience has shown there is no time during which one can feel entirely safe with its administration.

The chief use of the antithyroid drugs as reported in this article has been in preparing patients for thyroidectomy. When the treatment with these drugs is carefully managed subtotal thyroidectomy can be carried out without risk, and hyperthyroid reactions during anesthesia and after operation which in the past have caused great concern, are completely eliminated. Patients with milder hyperthyroidism, however are still prepared with Lugol's solution alone. These drugs are used until the full benefit is obtained, which is indicated by complete relief of all hyperthyroid signs and symptoms and return of the basal metabolic rate to nearly normal. Furthermore, it is advisable to keep patients at a normal metabolic level for a month or more before proceeding with thyroidectomy.

These patients now receive propylthiouracil and iodine simultaneously from the beginning of treat-

lanes in the membrane encapsulating the hematoma. Putnam found true 'giant capillaries' in the dural wall of the hematomas such as are nowhere else observed in the body. It stands to reason that repeated secondary hemorrhage may occur easily from these extremely dilated capillaries. This assumption is also supported by the observation that the erythrocytes in old subdural hematomas more than 2 months after the injury, looked well conserved and were hardly discernible from fresh blood.

The treatment of subdural hematoma is opening and evacuation of the sac.

THE PATHOGENESIS OF CONTROUPOUR INJURIES OF THE BRAIN

It is a well known fact that blunt traumas of the skull, as a rule, cause far more severe injuries of the brain on the side opposite the impact. The explanation usually given is that the brain hits the opposite wall of the skull by transmission of force. The author attempts to refute this theory. He discusses in detail the laws of mechanics involved in this problem and reports a great number of ingenious experiments done by himself, his collaborators and other men to study the effect of blows on a hard shell (bone iron) enclosing an incompressible substance with the physical properties of brain tissue. He tries to prove that the so-called contrecoup injuries are caused by the 'flying off' (Abschleuderung) of brain tissue at the pole opposite the injury rather than by the impact against the bony wall. To illustrate this phenomenon he quotes the well known eye injuries of blacksmiths when a blacksmith hits by mistake the steel anvil instead of the softer iron steel splinters flung off from the opposite end of the hammer head may cause perforation of the cornea and lens. The most interesting of his many experiments which seems to prove his point was this: half of a brain was enclosed in an iron tube which was open at one end and had a thick rounded bottom at the other. A hammer blow to the bottom caused the brain substance to fly off at the opposite pole. WERNER M. SOLMITE, M.D.

SPINAL CORD AND ITS COVERINGS

Cervicobrachial Neuralgia and Rupture of the Cervical Discs (Neuralgie cervico-brachiale et rupture des disques cervicaux) A. RICARD, P. F. GIRAUD, A. GARDI, and R. BRITTE. *Lyon. chir.*, 1947 42 513.

The primary object of this article is to draw the attention of the medical profession in France to the syndrome of the herniated disc in the cervical region. Naturally the literature on this subject from America has been extensively used, and in view of the fact that the subject itself has been clearly defined only since the outbreak of the war this article is most appropos. Communications with France and with the medical profession in that country have been established only recently. The reason for this preamble is that in the United States the subject dealt with so acceptably in this article is already on a firm footing in the minds of the physicians and surgeons here.

The authors' study is based on 10 cases of herniated cervical disc, 4 patients were operated upon and 6 were not. The case histories of the patients are presented along with the roentgenographic studies and operative findings. Various questions pertaining to the clinical examination are discussed and the statements of known American surgeons are quoted. The authors did not use lipiodol in their studies and believed that the lateral views of the cervical spine were of sufficient localizing value. Two of their patients, however, presented themselves because of pain in the face. The question of differential diagnosis is discussed, especially in regard to the syndrome of the scalenus anterior muscle. Contrary to opinion in the United States, the authors do not believe that vasomotor disturbance variations in the blood pressure or paresthesia on the ulnar side of the hand are characteristic of the scalenus syndrome.

Because of the operative procedure employed absolute localization was not essential. The authors' operation is a laminectomy of the fifth and sixth cervical vertebrae with intradural inspection of the offending disc. When the disc is found one of three alternatives is adopted: section of the posterior root over the disc, simple decompression or incision of the disc on the anterior surface of the cord with curettage of the disc. The last is seldom used. Localized arachnoiditis has been observed and is considered responsible for some of the neurological symptoms. The technique of the operation is described. It includes general anesthesia and the sitting position. ADRIEN VAN BROOKEW, M.D.

SYMPATHETIC NERVES

Surgical Therapy of Bronchial Asthma (Sulla terapia chirurgica dell'asma bronchiale) GERLANDO MARRA. *CHIRURG. ANN. ITAL. CHIR.* 1947 24, 447.

After having reviewed the different methods suggested and tried by different operators in the surgical therapy of bronchial asthma, the author refers to his results in 15 cases of severe asthma in which the patients were treated by means of an anesthetic block.

For the cases of bronchial asthma in which medical therapy fails the author advocates bilateral injections of alcohol into the stellate ganglion with extension to the superior cervical, and down to the second thoracic ganglion. The procedure may be repeated until optimum results are obtained.

This treatment should be preferred to operative intervention, because the latter is inaccurate and carries a surgical risk. ARTHUR F. CROILLA, M.D.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Blunt Injuries of the Skull and Brain (Ueber stumpfe Schadel- und Gehirntraumen) K. LEWYGERAUBER.
Hdvt. chir. abh., 1947 14: 543.

The author at the Surgical Hospital of the University of Bern, Switzerland, discusses three important factors with regard to blunt injuries of the skull and brain: (1) the mechanism of cerebral concussion (2) the subdural hematoma and (3) the pathogenesis of contrecoup injuries of the brain.

CEREBRAL CONCUSSION

It is a well established fact that not all major injuries of the brain are accompanied by loss of consciousness. According to a German article on shot injuries of the brain during the last war, more than 50 per cent of gunshot wounds did not bring about symptoms of concussion. Even destruction or severance of large parts of the cortex may occur without loss of consciousness. However, any blunt force hitting the skull vertically to its surface may induce concussion. It seems that involvement of the brain stem is necessary to bring about the typical symptoms.

Among the various theories which have been submitted to explain the mechanism of concussion, the author favors the old 'molecular' theory which assumes that the momentary increase of intracranial pressure causes minute molecular changes in the incompressible brain substance and brings about a transient 'stupor' of the cells in the brain stem. The author tried to support this theory by interesting experiments with fish which were exposed to explosions under water. He believes that these experiments refute the theories which consider edema of the brain or sudden pressure of the liquor against the fourth ventricle as the cause of concussion.

As to treatment of concussion, it is not advisable to do a spinal puncture unless critical symptoms develop. Just as we use pressure bandages in the treatment of frozen limbs to prevent the secondary edema, it is preferable from the therapeutic point of view to leave a certain degree of increased intracranial pressure as the counterpressure of the unelastic skull will check the development of brain edema. If however, spinal tap is necessary, the liquor should be drained very slowly and reinjected if the symptoms get worse as there is always the danger of herniation of the brain into the foramen magnum.

The author rejects intravenous injection of hypertonic solutions in the attempt to lower the intracranial pressure. The increase of blood volume leads to increased blood flow to the brain and, therefore, counterbalances the lowering effect of the hypertonic solution. In 6 patients, the spinal pressure was measured before, during, and after intravenous in-

jection of 200 c.c. of 20 per cent glucose. No lowering effect on the pressure was established in any case. Researches published by Wepl and Koenig, collaborators of the author, showed that isotonic and hypertonic solutions, when injected intravenously are eliminated from the circulation up to 50 per cent within 40 minutes and entirely after 2 or 3 hours.

Lyophilic serum (dried serum dissolved in a fourth of the original volume of water) is applied in quantities of from 50 to 100 c.c. and seems to be able to attract tissue fluid and so to lower the intracranial pressure. On the other hand it, too, increases the blood volume and, therefore, counteracts the lowering effect on the spinal pressure.

The application of magnesium sulfate by mouth or rectum (from 5 to 10 gm. t.i.d., or 50 gm. rectally in 100 c.c. of water) seems to be more effective than the intravenous osmotherapy.

SUBDURAL HEMATOMA

This condition is caused by rupture of the veins which course from the superior longitudinal sinus across the arachnoidal space. Most cases are of traumatic origin, although alcoholism or other pathological processes may cause rupture of the vessels without trauma. Wear and tear and chronic overstraining of these thin walled veins may lead to damage of the intima with secondary thrombosis and thus bring about subdural hemorrhage.

Diagnosis of subdural hematoma is a difficult problem because in the majority of cases symptoms do not develop immediately but after from 8 to 14 days, sometimes even after many weeks. The explanation given at present by most surgeons is that, due to the proximity of the cerebrospinal liquor the volume of the hematoma increases gradually by osmosis after the original source of hemorrhage has stopped. Experiments with blood enclosed in a cellophane bag and suspended in saline solution seem to support this theory.

Furthermore, as the blood in the hematoma sac is gradually broken down by hemolysis to molecules of smaller volume, the osmotic pressure is increased and more tissue fluid is attracted.

The author discusses a number of arguments against this theory of osmosis. He rather believes that the delayed development of symptoms like headache and somnolence is caused by the toxic action of autolyzed blood. He showed that sterile autolyzed human blood injected intradermally produces intense urticarial reactions and also some general symptoms. It is likely that histamine-like substances are formed by autolysis of blood whenever primary resorption of a hematoma is slow for some reason or other as in hemorrhages into the peritoneal cavity in a cyst of the thyroid, or in hemorrhagic periorchitis. These toxic substances originating in autolyzed blood cause extreme dilatation of the capil-

CHEST WALL AND BREAST

Phlebitis of the Anterolateral Thoracic Wall,
Mondor's disease (Phlébite en cordon de la paroi
antéro-latérale du thorax. Maladie de Mondor)
LUCIEN LÉGER. *Presse méd.*, 1947 55 849.

The author discusses an interesting syndrome seen in 22 patients. It is described as phlebitis of the thoracic wall noted most often in adult females between the ages of 25 and 55. The lesion is a cordlike band adherent to the skin and subcutaneous tissue with retraction resulting in an orange peel appearance in some areas. The structure occurs usually in the lower anterolateral chest region most often on the left side. The cord seldom is less than from 20 to 30 cm. in length and its diameter measures from 2 to 3 mm. Its consistency has been variously described as fibrous, indurated or cartilaginous. Its terminations gradually blend into the adjacent tissue, or two or more divergent strands may spread out from its lower most portion over the abdominal wall. In 3 cases double cords were noted along the left anterior axillary line.

This so-called thoracic wall phlebitis has an insidious onset. There frequently is pain, occasionally increased in severity by deep breathing. In some instances the linear cord is apparent only when the arm is widely abducted. There is no adenopathy and no abnormalities of the breasts have ever been noted. Roentgen films of the chest are normal and there is usually a leucocytosis with both monocytosis and eosinophilia. Bacteriological studies have been negative.

Histologically the lesions have the appearance of small veins and lymph vessels manifesting subacute obliterative endophlebitis associated with a certain degree of thrombosis. The vascular tissue in many areas is replaced by dense fibrous tissue. It has been postulated that the thoracoepigastric vein, the long superficial vein of the anterolateral thoracic wall, might be the anatomical basis for the lesion.

Benignity is the rule. The lesion persists for many years, one case having been followed for 8 years. Most patients are but little disturbed physically but in some the lesion is painful and in these cases extirpation is indicated. In those with marked cancerophobia, surgery is likewise justified.

OSVILLE F. GRIMES, M.D.

Amputation Versus Transposition of Gland and Nipple in Mammoplasty J. W. MALINZAC.
Plast Reconstr Surg 1948, 3 37

Essential requirements for the repair of a breast deformity are (1) injury to the gland and galactophorus ducts should be avoided or kept to a minimum in order that mammary function be preserved (2) the main blood supply to the breast must be preserved, particularly where extensive resection of hy-

Fig. 1 (Lucien Léger)

pertrophied tissues is involved in order to prevent necrosis of the skin and glandular structures (3) the resulting shape of the breast must be harmonious in all dimensions, and (4) scars should be slight and adequately concealed.

The procedure of amputation with excision of the nipple and its free transplantation to a new site according to the methods of Darligues or Thorek violates most of these premises, and is indicated only in huge hypertrophies with pronounced stasis. Even in many of the latter cases a less crippling procedure with preservation of the nipple can be successfully employed.

Following free transplantation of the nipple, no continuity of its ducts is restored. Physiologically the author states, this is tantamount to necrosis of both nipples. Normal sensitivity and contractility are absent or greatly reduced, and the mammary functions of the breast are lost—an important point particularly in unmarried girls and women who have not yet born children. Even with a complete 'take of the freely grafted nipple, a flattened configuration of the breast results from the use of a horizontal flap and the sacrifice of most of the glandular elements. In those rare cases of extreme enlargement, in which transposition would require too extensive incision, a one stage subtotal mastectomy can be done by removing the excess breast tissue from the posterior surface of the gland and excising the superfluous skin and fat along the midline and the submammary fold. The nipple itself is not disturbed and remains attached to the galactophorus system. In the occasional case of huge enlargement with edema and stasis of

of whom had hypertensive cardiovascular disease and all of whom were subjected to thoracolumbar sympathectomy in which the paravertebral ganglionated chain was resected from the seventh thoracic through the third lumbar ganglia, and the splanchnics were resected from the celiac ganglia to a point above the contribution of the seventh thoracic ramus. In certain studies additional interruption of nerve pathways supplemented the standard sympathectomy. Observations were made on the pain sensitivity of the stomach, large and small intestine, biliary tree, pancreas, and urinary tract prior to denervation, and at various times up to a year after right or left sympathectomy and after bilateral sympathectomy. All of the results reported were observed more than once and in some cases many times, and while it is realized that additional observations are desirable, the findings seem adequate at least for a preliminary report.

The small and large bowel was studied by balloon distention with a rubber bag attached to the end of a Miller Abbott tube. Varying volumes of air were used to induce painful stimuli. Illustrative diagrams are presented showing the areas of sensory reference.

Thermal stimulation was carried out by distending the balloon with warm (from 110 to 120°F) and cold (32°F) water. Direct stimulation of the stomach and intestinal tract through celiotomy was carried out on 6 patients who had previously had unilateral or bilateral sympathectomy. Tests of pain sensitivity were also carried out on the biliary tract, pancreas, and upper urinary tract.

Studies of visceral sensation before and after sympathectomy in which the splanchnics and ganglionated chains are removed from the seventh thoracic to the third lumbar ganglia on one or both sides show the following:

1. Pain sense in the stomach, intestine (except the rectum), extrahepatic biliary tract, pancreas, kidney

and ureter is mediated wholly by visceral afferent nerves which accompany sympathetic nerves within the area of the operative excision.

2. The kidney and ureter and the two sides of the colon have a homolateral sensory supply, but the remaining organs with the possible exception of the gastric mesentery have a bilateral supply.

3. Pain sensitivity exists not in the walls of the stomach and intestine but in the proximal mesenteries and at the mesenterovisceral juncture.

4. Adequate stimuli for pain include distention of the hollow viscera, traction and faradic stimulation of the stomach and intestinal mesenteries, and manipulation, traction, faradic stimulation of the extrahepatic biliary tract, pancreas, kidney pedicle, and ureter.

5. There is perception for extremes of temperature in the stomach; the afferent pathway accompanies the sympathetic.

6. The urinary bladder has a triple sensory supply via the visceral afferent nerves of the sympathetic and sacral parasympathetic systems and the somatic pudendal nerves.

7. Interruption of appropriate sympathetic nerves may be employed for the relief of intractable pain associated with some types of abdominal visceral disease.

8. The extensively sympathectomized patient may undergo certain alterations in his response to visceral disease because of the loss of visceral pain sense. So far none of the several hundred sympathectomized patients of the authors series have been known to develop acute appendicitis, cholecystitis, or any other abdominal surgical disease. However it is now the authors' practice to perform cholecystography on most patients who are to undergo sympathectomy for hypertension, if gallstones are discovered cholecystectomy is advised unless otherwise contraindicated.

HOWARD H. LAMER, M.D.

Fig 2 Safe and harmful glandular resections. 1. A, B, safe areas for wedge-shaped resection in the upper and lower lateral quadrants avoiding injury to the main vascular pedicles of the lateral thoracic and internal mammary arteries. 2. A, B' closure of glandular defects in safe areas and mastopexy to the pectoral fascia. (Affirmation of the gland is done at present along the posterior aspect of the breast.) 3. F, external resection of gland with upward rotation of an internal glandular pedicle—unsafe procedure (Gillies). 4. E, E' resection of upper half of the gland. F' extensive external resection (Biesenberger). These procedures are contraindicated because of the sacrifice of the main blood supply of the gland and possibility of necrosis.

main role in the vascularization of the gland and nipple. It follows that since in no individual case can the type of blood supply be foreseen the technique of choice of mammoplasty is one which preserves the blood supply in all types of vascular distribution. Notably unsound procedures are those in which the lateral or superior portions of the breast are resected since the lateral thoracic artery may be sufficiently compromised to lead to necrosis.

A two stage mammoplasty with transposition of the nipple as shown in figure 1 is advocated by the author as the safest procedure and one assuring an esthetic result.

One hundred and forty two cases with but a single instance of necrosis of the nipple postoperatively are reported by one author and Malinac has reported a further series of 103 patients with large hypertrophies none of which subsequently developed total necrosis of the nipple.

One disadvantage to the two stage procedure as originally described is a resultant excessive width of the breast. To remedy this difficulty the author has regularly done a wedge-shaped resection of the glandular elements at the second stage with the simultaneous removal of surplus skin through an incision extending from nipple to submammary fold as shown in figures 2 and 3.

In contrast to the effects of amputation lactation is always possible following the transposition procedure.

Fig 3 Nipple sutured in the upper pole of skin defect. S lateral flaps are shaped along the midline and submammary fold, m m. 2. Final reversed T-shaped suture line.

sure. Nipple sensitivity recurs postoperatively in 80 per cent of patients in from 3 to 6 months. In 20 per cent of the patients, the diminished nipple sensitivity following operation varies with the amount of glandular excision. WAYNE T. CAMERON, M.D.

Cystic Mastitis and Cancer of the Breast (Mastitis quística y cáncer de mama) ALEJANDRO J. PAVLOVSKY and ISIDORO M. CÁCERES BRATODANO. *Bol. Acad. argent. cir.* 1947 31: 909.

The importance of recognizing malignant lesions of the breast before the appearance of axillary metastases or other signs of advanced disease is reaffirmed. The alleged benign character of cystic changes in the breast is looked upon as giving false assurance. In young women presenting bilateral involvement by small cysts, a benign process can reasonably be accepted and corresponding treatment given. The same bilateral involvement by enlarging cysts, however, when the menopause is approaching should be looked upon with suspicion and indicates histologic study. Solitary cysts occurring unilaterally and, particularly of large size in women about 40 years of age should call to mind immediately the possibility of malignancy or preneoplastic change. Histologic examination followed by appropriate treatment is in order under these circumstances. Other more indirect methods such as the cytologic study of aspirated fluid may be misleading. Histologic study should be directed particularly to that part of the cyst wall in contact with the gland.

In the authors series of 111 breast cancers 12 or 10.8 per cent were cases of malignancy occurring in association with cystic mastitis. Most of them were found in women between 30 and 50 years of age. The authors' opinions are supported by 4 case reports and by photographs of the gross and microscopic features of the specimen presented.

HIRSH T. LANGSTON, M.D.

Fig. (Makins) Author's method I for the two-stage repair of hypertrophied breasts by a horizontal flap.

I st stage—Determination of new location of nipple. Horizontal lines are drawn across the clavicle (A) through the elbow joint (B) and half-way between A and B. Vertical line D is drawn through the middle of the clavicle. The intersection of lines C and D at E, determines the new location of the nipple. Outlining of anterior horizontal flap F, the lower border of which extends to the areola. G, excises skin on posterior and lateral aspects of breast to be excised. H, area of skin above submammary fold (a-a, b-b) to be preserved. I, first stage. II Shows denodation of the gland, excisions of lateral flaps (G) and removal of fat and glandular tissue from the lower pole (J). The illustration also shows superficial paring of fat and glandular tissue away from the nipple which since has been abandoned. N I that the vascular plexus around the reduced areola is retained also the thickness of the horizontal flap lined by

subcutaneous fat. III. Shows early concept of the blood supply in the breast. The lateral thoracic (T.L.) and external mammary (E.M.) branches of the axillary (AXL.) sending perforating branches to the external portion of the gland. Internal mammary (I.M.) and its perforating branches penetrating the inner half of the breast, (a) main perforating artery through the second intercostal space. For new concept of blood supply, see figs. 7, 8 and 9. IV Right breast shows closing of glandular defect following fixation of breast to pectoral fascia. Left breast shows nipple sutured in its new location, E, and skin flaps H and F loosely approximated and drained in place. V, 2nd stage. Right breast shows crescent-shaped excision of excessive skin, fat and glandular tissue along submammary fold. The hypertrophied structures can be in this stage freely excised without danger of impairing the vitality of the nipple. Left breast—final condition following closure of defect.

the nipple amputation is indicated by skin plasty and tattooing an artificial nipple can be created.

For the past several decades an erroneous conception of the blood supply of the breast (reprinted from one textbook to another) has led to complications subsequent to mammoplasty especially in cases of large hypertrophy in which extensive resection was

required. Anatomically it has been established that the blood supply of the breast derives from two vascular pedicles originating from the lateral thoracic and internal mammary arteries. In 55 per cent of all cases the lateral thoracic artery has an equal importance to the internal mammary artery and in 13 per cent the lateral thoracic artery has predomi-

decortication of the lung in 3 cases of tuberculosis complicated by chronic empyema.

In 2 of the cases, the results were very good. In the third although the result of the decortication was disappointing, the procedure was carried out with out any difficulty and the patient suffered no damage as a result of the operation. The cavity had been reduced to one-half of its previous size so that radical thoracoplasty was more effective.

The technique employed is described in detail
SAMUEL KARN, M.D.

Pleuropulmonary Manifestations of Amebiasis.
HIRAM T. LANGSTON AND ROBERT T. FOX. *Arch. Surg.*, 1947 55 618.

The authors present in brief a review of 10 cases of pleuropulmonary amebiasis seen over a period of one year.

All of these patients were veterans, but some of the men had not seen service in geographical areas of high infestation. These cases illustrate the fact that such conditions can clearly mimic any of the commoner forms of pleural, pulmonary, or other disease and since the amebae may be very difficult to demonstrate in the discharges, anti amebic therapy is frequently indicated on suspicion. The response to such therapy is specific and furnishes a diagnosis as well as treatment. Aspiration is used to relieve symptoms and hasten healing, but surgical drainage is not considered necessary as a rule as it is likely to prolong convalescence if improperly exhibited.

Six case histories and 4 illustrative roentgenograms are appended
HIRAM T. LANGSTON, M.D.

ESOPHAGUS AND MEDIASTINUM

Esophageal Stenoses Due to Caustics (Esterosis cáusticas del esófago). AUGUSTO LATOURE AODRE.
Rev. de Medicina 1947 7 81.

Reviewing the general features of cicatricial stenoses of the esophagus, the author points out that most of them occur as a result of ingesting the offending agent during periods of alcoholic intoxication. The most frequent caustics are commercial hydrochloric acid and alkalis. The symptomatology can generally be divided into two periods. The first occurs immediately after the ingestion of the agent and is characterized by vomiting (frequently containing blood), a general picture of acute poisoning accompanied by fever, headache and difficulty in swallowing with pain and burning. This lasts usually for a week if the dose has not been excessive. The symptoms abate as a rule, thereafter and the second phase of the symptom picture appears toward the end of the third week, this being the stenotic phase.

The pathology in the digestive tract includes the changes in the mouth, pharynx, and larynx, which may range from superficial burning to deep ulceration. A similar picture is noted in the esophagus, and its severity again is dependent upon the potency of the agent, ranging anywhere from superficial ulcers

to actual perforation of the esophageal wall. Sloughs of the esophagus may be expelled and more or less extensive areas of ulceration persist. The author points out that lesions of the stomach are probably more frequent than is usually supposed.

The diagnosis is usually based of course on the history in the acute stages, but the location of the more important lesions requires x ray study with contrast media. The author calls attention to the fact that spillage of the barium into the air passages is frequently due to incompetency of the glottis rather than to actual tracheoesophageal fistulas. In the earlier stages before cicatricial stenosis has occurred the barium may pass readily but leaves the irregular pattern characteristic of mucosal ulceration.

The treatment in the early acute phase is concerned with maintenance of nutrition, relief of symptoms and the management of any complicating features. The author does not use gastrostomy with out due deliberation. Maintenance of the esophageal caliber is carried out by instrumentation beginning relatively early even on the fourth and fifth days. This is done in order to prevent reductions in the esophageal lumen rather than to wait for their appearance and subsequent correction. An esophageal lumen of 7 or 8 mm in diameter is believed adequate. If the patient is seen after the development of stenotic lesions dilatations by bogies, blind or under esophagoscopy control, are carried out. If gastrostomy has been performed retrograde dilatations may likewise be undertaken. A certain amount of technical detail concerned with the dilatations is given. The intractable stenoses are referred for corrective surgery.

The complications of course, include the immediate toxicity of the acute phase, the possibility of pyloric stenoses occurring as a result of gastric lesions and those complications which result from mediastinitis caused by perforation of the esophagus. The point is made that the cicatricial area is not apt to perforate on instrumentation but that perforations occur in a more normal adjacent portion of the esophageal wall. Another complication which may or may not be the result of instrumentation is the occlusion of the esophagus, total or subtotal which may require emergency management if spontaneous relief does not occur. The general picture of suppurative mediastinitis is described and allusion to its satisfactory management by the use of antibiotics is made.

Brief data on 41 patients with esophageal stenosis who were seen during the past 4 years are given. There were 23 males and 18 females. There were only 3 children. Of the 41 patients 19 were treated by the author from the beginning while 22 of them arrived late for treatment. There were 3 deaths in the first group and 8 in the second. The incidence of pulmonary tuberculosis is suggested as being relatively high in these patients.

The article is accompanied by several brief case abstracts and illustrative roentgenograms.

HIRAM T. LANGSTON, M.D.

TRACHEA, LUNGS, AND PLEURA

Pulmonary Arteriovenous Aneurysm. WILLIAM LAW
Watson Surgery 947 9-9.

The literature contains reports of only 10 cases of congenital or nontraumatic pulmonary arteriovenous aneurysms. Since the lesion consists of a lobulated thin walled, branching blood filled, pulsating pulmonary sac of varying size made up of both an arterial and a venous component, it seems reasonable to call it a pulmonary arteriovenous aneurysm, in order to distinguish it from benign hemangioma of the lung, metastatic pulmonary hemangioma of the lung, and hemangioendothelioma of the lung.

The diagnosis is suggested by a syndrome characterized by cyanosis, clubbing of the fingers and toes, secondary polycythemia, and symptoms of anoxemia, usually in a young patient with an obscure lung tumor and a normal heart. A bruit may be heard over the tumor.

It seems certain that trauma does not play an important part in the etiology as a history of injury was recorded in only one case. It must be assumed that a gradual expansive enlargement and thinning out of the walls of the vascular tumor takes place slowly over a period of years, and that spontaneous hemorrhage occurs when overextension increases the pulmonary pressure enough to cause a break.

Pulmonary arteriovenous aneurysms are congenital and mechanical defects in the relationship between the pulmonary arteries and veins, and as such are not amenable to medical therapy; they can be relieved promptly and dramatically by adequate surgical extirpation of the involved portion of the lung. There has been no reported operative mortality and the postoperative lung function studies indicate a return to normal factors.

Before operation there is marked hyperventilation at rest during moderate exercise and on recovery from exercise. The arterial oxygen unsaturation found at rest increases during moderate exercise. After operation, the high hematocrit and red blood cell volume decreases to normal and the arterial oxygen saturation improves.

Two additional cases are reported.

SAMUEL KAHN, M.D.

Cavernostomy. E. J. O'BRIEN, P. V. O'ROURKE, F. C. TERRY and E. F. SKINNER. *J. Thorac. Surg.* 947 6 602.

When the usual measures of collapse therapy are ineffective for cavity closure, cavernostomy is often used successfully for residual cavities after thoracoplasty. In 6 of 11 patients with such cavities, the condition was apparently arrested, the cavity closed, the wound healed, and the sputum became negative for tubercle bacilli. In another patient the condition was improved, the sputum became negative, the wound was reduced to a small sinus, and the cavity closed or was not definitely visible.

After unsuccessful trial of the usual procedures of collapse therapy cavernostomy is usually effective

in closing lower lobe cavities in patients with adequate cardiorespiratory reserve. In 5 of 6 such patients, the condition was apparently arrested.

Cavernostomy may be a useful procedure for patients without dyspnea or progressive tuberculosis when reduced function of the opposite lung prohibits collapse therapy or pulmonary resection. Open cavity drainage produced apparent arrest of the condition in 33 per cent, and improvement in 27 per cent of 15 patients in this group. In patients with obvious dyspnea or progressive tuberculosis, cavernostomy yields few good results. In 36 such patients, the operation was followed by apparent arrest of the condition in 3 per cent and by improvement in 14 per cent.

Healing of the wound and the cavity appeared to be most prompt when cavernostomy was preceded or accompanied by some surgical collapse of the involved pulmonary tissue. Most of the deaths and serious complications occurred in patients who had poorly resented advancing tuberculosis, or who were visibly short of breath prior to the cavernostomy.

SAMUEL KAHN, M.D.

Carcinoma of Cavities of the Lung. Its Evaluation and Importance for the Physician. (Des Kavernarkarzinom. Seine Bedeutung fuer den Arzt und fuer die Begutachtung.) SEYMOUR GRANT.
Dtsch. med. Wochschr. 1947 73 405.

Carcinomas may develop as primary tumors in the wall of a tuberculous cavity in the lung. Their occurrence is not extremely rare, but is apt to be overlooked in many cases. No case has ever been diagnosed intra vitam. Even in autopsies, the diagnosis can be missed easily as it is difficult to differentiate the tumor from the surrounding necrotic and caseous tissue. In all observed cases, the tumor originated from the border area between the bronchus and the wall of the cavity. It may cause metastases to the regional lymph nodes, the kidneys, liver, brain, thyroid and bones. Microscopically, the tumor reveals the picture of a squamous-celled epithelial carcinoma.

The author reports 6 cases observed at the Pathology Institute of the General Hospital Barmbeck in Hamburg Wandsbeck. All cases occurred in men between 43 and 63 years of age.

The role of tuberculosis as the causative factor and the medicolegal problems connected with it are discussed.

WILHELM M. SCHMIDT, M.D.

Decortication in Chronic Empyema of Tuberculous Origin. FRANK B. GORD. *J. Thorac. Surg.* 947 6 587.

In view of the relative frequency with which chronic empyema complicates pulmonary tuberculosis, the unsatisfactory results obtained by methods of treatment other than decortication (including extrapleural thoracoplasty and operations of the Schede type) and the crippling deformity which follows in those who survive extensive operations for collapse of the chest wall the author performed

The esophageal cysts however often lie close to or within the wall of the esophagus. Thus attempts to excise these cysts involve a risk or injury to the esophagus and dangerous complications. The intrathoracic enterocystomas occur for the most part on the right of the midline.

Symptoms from these mediastinal enterocysts can be traced to (1) direct mechanical pressure of the cyst on neighboring organs such as the blood vessels, heart, esophagus, trachea, and bronchi and (2) complications which rapidly increase the volume of the cyst, such as infection or hemorrhage. The diagnosis is easy to make for it is generally made after complications have developed and led to a thorough examination of the thorax, particularly with the roentgen ray. There are cases however in which the diagnosis has been made after an incidental roentgen examination.

The method of treatment is operation not only in the case of acute complications during the first few months of life but also in every case in which the development of complications or incidental or routine roentgen examination shows that a mediastinal formation is probably or undoubtedly present. The best approach to the field of operation in most cases is that used for pneumonectomy.

MISCELLANEOUS

The Treatment of Thoracogastric Fistula G. E. LINDSKOG AND E. A. LAWRENCE. *J Thorac Surg* 1947 16 477

A fistula between the stomach and the left pleural cavity or chest wall may develop spontaneously as the result of perforation in a peptic ulcer or cancer either when the stomach is in normal intra-abdominal position or more frequently when the stomach is herniated into the thoracic cavity. A thoracogastric fistula may also develop acutely as a complication of wounds involving the diaphragm and stomach. Rarely a thoracogastric fistula results from ill-advised surgical intervention when the existence of a diaphragmatic hernia with incarcerated stomach or eventration is not recognized and the surgeon at fault performs an intercostal trocar-catheter drainage under the misapprehension that a pleural effusion or empyema exists. The authors present 3 cases of this last type.

The first case was that of a 30 year old man who had been injured in an automobile accident 6 years previously. He had a fracture of the pelvis and of a left rib. Because of fluid in left pleural cavity with probable empyema a catheter was inserted and a dissecting infection of the chest wall subsequently resulted. When the drainage had stopped the catheter was removed and the chest wall healed. Five years later he developed left sided pain. Physical examination and roentgen ray studies revealed an opaque area pushing the heart to the right. Operation disclosed that the pleural cavity contained the stomach, left side of the colon and many loops of small bowel.

On reducing the viscous a defect in the central portion of the diaphragm was seen extending into the esophageal hiatus.

The second case was that of a 26 year old man who was also in an automobile accident, and who sustained injury to the left side of his chest. Blood accumulated in the chest which was removed by thoracentesis and intercostal catheter. Five months later he became ill. The catheter was still in the chest. The left lung was almost totally collapsed, the mediastinum was shifted to the right, and the transverse colon was displaced to the right. Barium by mouth appeared rapidly in the pleural cavity. At operation the stomach and part of the colon was seen through a diaphragmatic defect and reduced. Closure of the diaphragm was effected with silk sutures.

It is considered timely to report these experiences now because diaphragmatic hernia is a well recognized albeit uncommon complication of military and civil trauma. It should be recognized that blunt trauma to the chest and upper abdomen or a squeezing type of injury may by indirect bursting violence to the diaphragm particularly on the relatively unprotected left side, cause a laceration to appear in the thin central portion sometimes extending into a normal hiatus, commonly the esophageal hiatus. Such lesions are easily overlooked in the period of acute reaction to trauma because of surgical shock, the existence of other more obvious external trauma, or the presence of an obscuring hemothorax on the affected side. It should be emphasized that such a diaphragmatic rupture can occur in the absence of fractured ribs.

STEPHEN A. ZEEMAN, M.D.

Pulmonary Edema: Experimental Observations on Dogs following Acute Peripheral Blood Loss. ROBERT M. EATON. *J Thorac Surg.*, 1947 16 668.

Acute hemorrhage of 25 per cent of blood volume from the femoral artery of dogs has resulted in the following circulatory and pulmonary changes:

1. A temporary imbalance in the circulatory system in which there is an elevation of pulmonary artery pressure and peripheral venous pressure with no comparable elevation in the low systemic arterial pressure which follows acute hemorrhage.

2. A block to normal circulation within the lung which is acute for an hour or more and partially effective for several days.

3. A predictable pattern of pulmonary moisture change within a four hour period following hemorrhage, characterized by (a) an initial rise in pulmonary moisture during the first 30 minutes, associated with a drop in the plasma protein level and an elevation of the hematocrit reading (b) a drop at 45 minutes to levels below normal pulmonary moisture while the plasma protein level continues low and the hematocrit reading is slightly elevated (c) a second rise in pulmonary moisture above normal averages at 1 1/4 hours with plasma protein findings at their lowest and the hematocrit reading above normal (d) a leveling off toward normal pulmonary moisture at 4 hours with the plasma protein level low.

Esophageal Stricture following Agranulocytosis Due to Sulfonamide Therapy BURTON D. BRYAN. *N. England J. M.* 947:237-94.

Sulfonamide therapy carries with it the threat of depression of the centers of blood formation with resulting agranulocytosis, and thus of agranulocytic angina. Should the process that sets up this angina extend to the esophagus, acute esophagitis results.

A case of marked esophageal stenosis following agranulocytosis due to sulfonamide therapy is reported. It is assumed that the same process that caused the severe angina of the mouth also caused ulcers in the esophagus, and that after the acute esophagitis had resolved secondary cicatricial stenosis took place.

Had the nature of the esophageal lesion been appreciated sooner, bougienage at an earlier date might have prevented the resulting stenosis.

SAMUEL KAHN, M.D.

Gastrogenous Mediastinal Cyst. LOUIS R. DAVIDSON AND LOWELL BROWN. *J. Thorac. Surg.* 947:6-458.

This is the twenty-second case of gastrogenic mediastinal cyst recorded in the literature. The cyst was found during the course of a routine physical examination of a 5½ year old girl.

Examination at this time showed a well developed girl who was somewhat underweight. The only abnormal findings appeared to be dullness and diminished breath and voice sounds over the right lower lobe posteriorly.

At operation a large cyst of the posterior mediastinum measuring approximately 9 cm. in diameter was found. It extended from the third rib superiorly to about an inch above the diaphragm inferiorly, and was closely adherent to the posterior aspect of the upper half of the lower lobe posteriorly. The cyst was purposely tapped and its thin opalescent, light, coral-colored fluid was aspirated. It was then excised by blunt and sharp dissection. Inferiorly it appeared to be attached to the right side of the esophagus in close proximity to the diaphragm.

The postoperative course was entirely uneventful and the patient was discharged on the twenty first postoperative day. The final checkup roentgenograph showed the lung completely re-expanded.

An analysis of the 22 cases is given in table form. It is seen that these cysts have occurred primarily in infants and young children. One patient was 23 years of age and another 15 years; the rest of the patients whose cases are recorded have been under 5½ years of age at the onset of their symptoms or at the time of operation. Fourteen of the patients were males as against 7 females.

The location of the cysts has been remarkably constant. In 18 of the 21 patients the cyst was located in the right hemithorax, and in 17 patients it has been definitely located posteriorly.

Diagnosis remains an extremely difficult task. There is no symptom or symptom complex which is pathognomonic, several cases having been practically asymptomatic.

Aspiration has been used as a diagnostic as well as a therapeutic procedure. Fifteen of the 21 patients were submitted to operation and 9 of these recovered. Four of those recovering were treated by a stage operation with marsupialization and 4 by primary excision. There seems to be no question that operation is advisable in all cases, both because the exact type of tumor to be dealt with is usually not definitely known preoperatively and because these tumors almost always cause symptoms quite early in life. The high mortality is not surprising. Many of the patients are infants in extremely poor shape, and in these cases a stage operation with marsupialization of the cyst has in the past sometimes seemed most wise. With modern advances in the preparation of patients for operation, and with improved techniques for the administration of anesthesia, a one stage removal of the tumor will almost always be the procedure of choice.

The experience of Ladd should be kept in mind when attempting excision of these cysts. In one of his cases, a gastrogenous cyst shared a common muscular wall with the esophagus. Complete excision of the cyst resulted in an esophagopleural fistula with subsequent fatality. STEPHEN A. ZIEGLER, M.D.

Mediastinal Enterocystoma. NELS LINDBQVIST AND HELEN B. WOLFF. *J. Thorac. Surg.* 1947:16-468.

Mediastinal cysts of the enterocystoma type with mature gastric mucosa are most rare. The author reports the case of an infant 7 months of age, in whom the cyst was found when roentgen examination was made to determine whether or not the child had bronchopneumonia. Following recovery from the acute chest condition, operation was performed and a tumor the size of the entire upper part of the right pleural cavity apically and mediastinally, was removed. Recovery was complete in 2 weeks time.

Cystic formations of congenital origin (enterocystomas) occurring at different places along the alimentary tract and nearly always immediately adjoining it, are not particularly uncommon. They are lined with the various forms of mucous membrane occurring in different locations in the alimentary tract. The type of mucous membrane lining a cyst need not correspond with the part of the alimentary tract in which the cyst is situated, or with which it is intimately connected. It is also interesting from a surgical standpoint, that the muscular layers coating the cyst are often adherent to and sometimes comprise an integral part (microscopically) of the muscularis mucosae of the alimentary tract. As a rule, the cysts are well delimited from the actual lumen of the digestive tract. Sometimes, however, there is a direct communication. It is because of these two alternatives that the cyst sometimes contains the same matter as the alimentary tract and at other times contains a nonspecific watery fluid or fluid containing hydrochloric acid and pepsin.

The commonest situation for intrathoracic enterocyst mas is in the posterior mediastinum, often in fairly intimate contact with the pulmonary hilus.

SURGERY OF THE ABDOMEN

GASTROINTESTINAL TRACT

Contribution to the Knowledge of the Surgical Forms of Gastric Tuberculosis (Contributo alla conoscenza delle forme chirurgiche della tubercolosi gastrica) RAFFAELI NICOLÒ. *Gior ital chir* 1947 3 446

Tuberculosis of the stomach is relatively rare, but rarer still is its so-called surgical form and also its high localization as the literature consists mainly of pyloric and juxtapiyoric cases. Therefore, Nicolò reports a case of ulcerocicatrical type in which the lesion was located on the lesser curvature 6 or 7 cm. below the cardia in a man of 52 who had already been subjected to gastroenterostomy. The intervention consisted of removal of the lesion by saddle resection and longitudinal suture of the lesser curvature after verification of the integrity of the previous gastroenterostomy. Koch's bacilli and typical tubercles were demonstrated in the removed specimen.

The hematologic route and spread by contiguity seem to be the most frequent pathogenic mechanisms of the disorder. In the present case roentgen examination revealed signs of an old pulmonary lesion but no lesion in other localizations and it was thought that in all probability the gastric infection had occurred by the hematologic route. Anatomopathologically the lesion belonged to a mixed form the ulceroinfiltrative, because of the presence of great loss of substance and of intense proliferative and fibrous phenomena in the serosa. In this connection it is interesting to compare peptic with tuberculous ulcer keeping in mind that microscopic examination alone will lead to the correct diagnosis. While peptic ulcer decreases in size as it passes from the mucosa to the muscularis and the serosa, tuberculous ulcer has a larger diameter deeper down than at the mucosa and resembles a reversed funnel because the submucosa is more involved than the mucosa thus the borders of the tuberculous ulcer are usually undermined sometimes ragged and reddish, but rarely hemorrhagic.

The diagnostic criteria of tuberculous ulcer are very relative as the symptomatology of peptic ulcer is found in some cases and that of carcinoma in others. Of some importance would be an evening temperature the coexistence of tuberculous lesions in other organs and the presence of an epigastric tumor without any other characteristics of carcinoma, including age of the patient, as gastric tuberculosis is more frequent in the young. However all of these data may be absent as in the present cases in which the symptoms were those of typical peptic ulcer while objective examination and anamnesis revealed no trace of tuberculosis in other organs. The diagnosis of gastric tuberculosis is therefore nearly always retrospective. The roentgenogram is

of no help because in most cases it shows only signs that are hard to differentiate from those of carcinoma, and from those of peptic ulcer in a few cases.

Resection would seem to be the best intervention because the coexistence of gastric tuberculous and blastoma (carcinoma sarcoma, or lymphosarcoma) is not rare. However in the present case local and general considerations suggested limitation of the intervention to ample excision of the infiltrated and ulcerated tract after liberation of the adhesions to the pancreas. Excision is followed by longitudinal suture of the defect. Two years later the patient was found to be in excellent health and without any gastric disturbances.

RICHARD KEMEL, M.D.

Acute Perforation of Gastric Carcinoma (Sulla perforazione acuta del cancro gastrico in peritoneo libero) GIOVANNI FORNI. *Arch. Ital. mal. app. dig.*, 1948, 14: 54.

Perforation of a gastric carcinoma in the peritoneal cavity is not exceptional but merits more consideration. It is found most frequently in men (87%) between the ages of 50 and 60 years. Some of the factors are as follows: (1) general—age and sex (2) local—the type of tumor and (3) the determining factor—rapid distention of the stomach. The perforation is almost always single and is most frequently present on the anterior surface of the antrum.

The diagnosis should take into consideration the age and general condition of the patient and the symptomatology.

Resection is the treatment of choice giving the lowest mortality rate.

The prognosis is always grave and the mortality is high.

ARTHUR F. CIPOLLA, M.D.

Irradiation of Gastric Cancer G. CRANSTON FAIRCHILD and ALAN SHORTER. *Brit. J. Radiol.*, 1947 20 511

The authors have combined the surgical and radiologic approaches to the treatment of cancer of the stomach. Irradiation is administered with the abdomen open and directed to the cancerous tissue. Biopsy specimens are taken to help confirm the diagnosis. An accurate and effective dose of radiation at high intensity is given directly to the tumor and field of local spread without irradiation of the large volume of normal tissue including the vital organs and skin which is unavoidable when irradiating from the skin surface. This is of importance in an already anemic and cachectic patient. Operations to relieve obstruction, if necessary, can be performed before the irradiation at the same or an earlier and less extensive laparotomy. Although the obstruction may not be severe it increases because of fibrosis of the tumor following irradiation. Irradiation of normal viscera is avoided as far as possible by displacement and packing of the field. A special sterilized appli-

and the hematocrit reading above normal expectancy.

4. Recent histopathologic studies suggest that in some animals this adjustment of fluid economy after hemorrhage is temporary. Pulmonary edema has been observed histologically 5 days after blood loss during which there has been normal activity.

5. An aggravation of the pulmonary edema of acute peripheral hemorrhage results from the intravenous use of either physiologic sodium chloride, whole blood, or plasma. When physiologic sodium chloride is administered the increase in pulmonary moisture is twice that found when either whole blood or plasma are used following similar blood loss. Plasma protein levels drop when physiologic sodium chloride is used, while these levels are maintained fairly well when whole blood or plasma are given.

6. An increase in pulmonary transudation is noted by a marked stimulation to pulmonary lymph flow.

7. Histopathologic lung changes of edema, congestion, and hemorrhage are evident as soon as from 10 to 30 minutes after blood loss, and have been noted to persist for several days.

8. The pulmonary edema resulting from acute peripheral blood loss is a stagnant alveolar accumulation of high protein value. This may be an ideal culture media for droplet implantation from the nose and throat and for the subsequent development of pneumonia.

JOHN J. MALONEY M.D.

The Use of Fluorescein to Demonstrate the Effect of Artificial Respiration upon the Circulation.
SAMUEL ALCOTT THOMPSON, EURY LANCX, AND
EDWARD EDWIN ROCKEY. *J. Thorac. Surg.* 1947
6: 710.

Inflation and deflation of the lungs in a previously heparinized animal immediately after death produces a movement of the blood column within the vascular system. This can be observed by the intravascular injection of a tracer substance, fluorescein which gives a typical luminous appearance when examined under an ultraviolet light. The movement of the blood is in a normal direction and as such can be circulated over the entire body. This movement of the blood takes place without the benefit of any cardiac activity.

The widest and quickest distribution of the dye occurred when alternating positive and negative pressure resuscitation was used.

The importance of heparin in resuscitation is demonstrated. Heparin keeps the blood in a fluid state and as such allows it to be circulated. Once clotting has occurred no further circulatory movement is possible and all resuscitative attempts will fail.

Resuscitation with alternating positive and negative pressures is superior to resuscitation with either positive pressure or negative pressure alone.

JOHN J. MALONEY M.D.

terminate the first seroserosal suture. There should be no tension at the duodenal level and in particular not of the mesoduodenum. The duodenum is liberated and the gastroduodenal ligament repaired. Recently the authors have infiltrated the mesoduodenum with novocaine. The abdomen is closed over a drain in the subhepatic region which is removed on the tenth day.

The objection to the Péan anastomosis that it does not permit a sufficiently extensive gastrectomy is not justifiable. The gastrectomy should be made as extensive as indicated without regard to the type of anastomosis.

The present series of 100 patients included 80 males and 20 females ranging from 33 to 65 years of age, with the greatest frequency between 40 and 50 years. There were 75 with gastric ulcers including 16 of the lesser curvature at the gastric angle, 37 in the middle of the vertical portion, 7 of the posterior deciduity, 2 of the posterior surface and 3 in the juxtapyloric region. In 8 cases the ulcer spread to the pancreas and was associated with middle gastric stenosis in 2 cases and with pyloric stenosis in 1 case. There were 6 duodenal ulcers, 10 double ulcers of the lesser curvature and duodenum, 4 pyloric ulcers, and 3 jejunal ulcers following gastroenterostomy. There was 1 case of massive recurring gastrohemorrhage.

The postoperative complications of the Péan anastomosis seem less numerous than those following the Finsterer operation. They included 8 pulmonary complications (one bilateral and fatal), 1 case of pleurisy, 1 case of pulmonary embolism on the fifth day with recovery, 3 cases of watery or black vomitus with fetid regurgitations requiring gastric lavage.

Of the 5 deaths, only 3 could be attributed to the operation, autopsy revealing partial necrosis in the duodenal wound. In one of these cases the suture came in contact with the curetted base of the ulcer. In one case death occurred from intractable hemorrhage in spite of multiple transfusions. The Péan operation is not suitable for cases in which hemorrhage has caused vascular hypotension. The fifth death occurred in a woman of 65 years with bilateral pulmonary complications.

It is suggested that death from peritonitis might be avoided by more careful selection of patients and rigid observation of the requisite anatomic conditions. Four of the deaths occurred in the earlier period of the authors' experience. In desperate cases, dehiscence might be forestalled by suppression of all fluid nourishment, continuous aspiration of the fistula combined with immediate jejunostomy and abundant subsequent parenteral rehydration.

At present the indication of choice for the Péan anastomosis is ulcer of the lesser curvature. However ulcers of the surfaces, in particular the posterior surface, respond nicely to this technique if they are not too high up.

The Péan anastomosis is contraindicated in ulcer of the duodenum, gastric cancer, fulminating ulcers of the posterior surface externalizing into the pancreas, badly infected ulcers or recently healed per-

forations. In cases of profuse hemorrhage and anemia the Finsterer or Polya operation would seem preferable.

While the immediate advantages of the Péan procedure as described here appear not too striking the authors hope in a future publication to show that the end results justify the added risk involved.

EDITH SCHWARTZ MOORE.

Psychosomatic Considerations in Peptic Ulcer

MANUEL D. ZAMER, *Psychosomatic M.*, 1947 9 372

A punched out defect, the size of a quarter on the lesser curvature of the stomach or adjacent duodenum is a real thing objectively to the roentgenologist or gastroenterologist, and subjectively to the patient because of the writhing pain. This is a situation which the authors believe has been brought about by an underlying conflict in which the individual feels compelled to function in a certain manner despite anticipation of failure. As indolent peptic ulcers are created by conflict situations chronic as well as acute ulcers heal rapidly when the conflict situation is removed.

The peptic ulcer conflict situation involves both fear and resentment, each of which has opposing effects on the stomach and duodenum. When fear and resentment are experienced simultaneously the reactions in the stomach are dissociated and often result in increased acid motility and vascularity with decreased mucus. It is postulated that during such dissociation other protective substances and mechanisms are likewise deficient in the presence of increased acid and pepsin. Such physiologic concomitants to this conflict situation are highly conducive to the development of ulceration.

The ulcer diathesis resides in the basic character structure which readily thrusts the patient into the peptic-ulcer type of conflict situation. If this situation is of short duration the symptoms will also be brief. If sustained they will be prolonged.

The variations in gastroscopic findings are best integrated by the psychosomatic concept, which assumes both that the emotions affect the color and appearance of the stomach and that changing emotions are accompanied by prompt changes in the appearance of the stomach. Varying gastric juice and acid levels during the day and night are explained by the changing emotions experienced. Seasonal recurrence and frequency of recurrence are all related to the character structure of the patient.

The diagnosis of peptic ulcer is supported by finding a character structure which readily thrusts the patient into the peptic ulcer conflict situation.

The emotional reaction of the patient is held to be of greater significance than the particular diet or drugs utilized in the treatment. This does not preclude the possibility of developing measures to correct the anatomic imbalance in the stomach and duodenum associated with the ulcer type of conflict.

The concept according to this article that peptic ulcer is a psychosomatic disease, affords a better understanding of the many confusing manifestations of

cator is introduced into the wound to protect the skin edges. To avoid shock produced by frequent moving, a special trolley has been designed on which the patient can have both the operation and irradiation.

In summary of 33 patients, 15 were treated by direct irradiation. In 8 of these the disease appeared to be limited to an area that could be irradiated. Of this group one lived 24 months after treatment, 3, 15 months, one 7 months, one 4 months and one 3 months.

Although this series is small, the authors believe that direct irradiation at high intensity will prove to be a rational and important advance in the treatment of cancer of the stomach and other viscera. Although wider exposure is needed than for surgery alone, with adequate precautions the whole procedure should not be so shock-producing as wide surgical excision.

Since there was no precedent to indicate the probable effects of high tumor dosage given within a minimum of from 2 to 5 minutes, the earlier patients were treated with smaller doses than those that could be expected to be curative alone. Therefore these patients had supplementary external irradiation beginning within 10 days of the operation. Some had further external irradiation months later. The initial dose has been gradually increased, two tubes being used together to a maximum (to date) of 3,000 roentgens in 3 minutes over a field of 13 cm. minimum diameter. The authors hope eventually to be able to give an adequate initial dose so as to dispense with the later external irradiation. It is suggested that the hospital of the future will have a radiotherapy room adjoining the operating theater to facilitate direct irradiation in cases of inoperable carcinoma.

HAROLD LAUFMAN, M.D.

The Statistical Approach to Gastric Cancer. DIXON JENNINGS. *Brit J Radiol* 1947 20: 53.

Carcinoma of the stomach is the most important form of cancer in Western civilization. It probably accounts for about a fourth of all deaths due to cancer in individuals under the age of 70. The author attempts to bridge the gap which exists between the public health picture of the disease and the more personal picture which hospital records and individual experience present. An extensive statistical analysis is made which compares the incidence of gastric cancer in England and in the United States. It shows a remarkable parallel between the two countries. Diagrams are presented giving the age, sex, class and geographic distribution of gastric cancer, insofar as it can be depicted from available vital statistics. In some country districts it is difficult to persuade elderly patients to report to a hospital, and thus statistics are not always accurate. Of the patients referred to a hospital, more than half probably receive a surgical opinion, about a fifth have too advanced a condition or are suffering from some heart or chest condition which makes surgery impossible. Operability rates are inaccurate since many provincial surgeons prefer to confine their surgery to

types of disease with low operative mortality and a quick recovery. The surgeon in a big city has far greater freedom of action than his colleagues in a small one. Of from 3,000 to 5,000 patients referred to a hospital, from 1,000 to 3,000 will probably be laparotomized. From 300 to 1,000 will be subjected to some form of gastrectomy, and from 200 to 500 of these will survive the operation, but by the end of 10 years from 40 to 100 only are still surviving. If it is remembered that 100 per cent 10 year survival cannot be expected of patients subjected to gastrectomy as the average age is probably over 60, the long term survival rates after gastrectomy compare quite well with the results of radical operation in other forms of cancer.

The results in gastric cancer are bad at present, partly because of the age of the population affected and partly because of the long delay before operation. A study of cancer records in any big hospital shows that some of this delay could be avoided. More examinations, especially between the ages of 40 and 60, should be made and repeated. Furthermore, the radiologist and gastroscopist should work more closely together. There are no carefully planned statistical experiments to prove that one form of treatment is better than another.

HAROLD LAUFMAN, M.D.

The Péan Gastroduodenal Anastomosis after Gastrectomy; 100 Operations (Anastomose gastro-duodénale à la Péan après gastrectomie; a propos de 100 opérations). E. DELANNOY and G. LAGACHE. *Rev. chir.* Par. 1947 66: 93.

The indications and immediate results of the Péan gastroduodenal anastomosis following gastrectomy are discussed on the basis of 100 cases.

In order that this anastomosis may be done the duodenum must be intact. The mobility of the duodenum can be improved by detachment of the pancreas. Because of the better vascularization of the posterior surface, the authors prefer a right to-left gastrectomy with primary direct hemostasis to a left to-right procedure or gastric hemisection. An extremely thin, narrow falcid duodenum may constitute a contraindication to the Péan technique, but a thin duodenum frequently thickens on retraction following section, and its caliber may also be increased by a longitudinal incision of exactly 1 cm. in the middle of the anterior surface. The technique of the operation is described in detail with schematic drawings. Special precautions are urged to prevent injury to the wound margins and bloody effusions. For the gastrectomy the classic right to-left technique is used. The authors' technique for the gastroduodenal anastomosis closely resembles that of Allaines and is illustrated by schematic drawings. Special care is devoted to suture at the angles, a serosal "U" suture being employed at the inferior angle while at the superior angle a musculoserosal suture including successively the posterior and anterior gastric margins and anterior duodenal margin is used, and a second seroserosal suture is used to

From an etiological standpoint the stenosis may be caused by congenital anomalies as well as by acquired intraduodenal or extraduodenal diseases.

According to some writers the duodenum is normally slightly compressed and narrowed under the root of the mesentery and consequently a tendency to obstruction will result if the lumen is further diminished.

The author mentions the congenital causes of duodenal obstruction and refers to their types and mechanism.

Among the acquired causes of duodenal obstruction, apart from tumors mention should be made of gallstones which have perforated to the duodenum and subsequently impacted themselves either in the superior part of the duodenum or at the duodenojejunal flexure and produced a total or partial obstruction there. Apart from the choledochus the calculi most frequently leave the bile ducts through perforations of the duodenum next through the colon, and finally through other organs.

In other instances the calculi were not in themselves large enough to obstruct the lumen however they caused such an inflammatory hyperplasia of the pylorus as to obstruct the passage.

The author has had the opportunity to observe 3 cases of duodenal stenosis, 2 of which are reported.

Only a few cases of gallstones as the direct cause of obstruction of the duodenum are reported in the literature, and the author has therefore deemed it appropriate to recapitulate briefly the cases which he has succeeded in tracing in the literature.

It is seldom possible to map out the very cholecystoduodenal passage. When symptoms have been present they have taken the form of intensive stabbing pain thus resembling initially a perforation.

A brief account is given of the relation between megaduodenum and ulcer. HARRY W. FINE, M.D.

Study of the Vascularization of the Colon and the Anastomotic Arcades (Contributo allo studio della vascularizzazione del colon le arcate anastomotiche). ANDREA BERTOCCHI *Chirurgia* 1947 2 193.

The collateral vascularization of the mesenteric artery is of two types (1) dichotomic or consisting of two branches and (2) in arcade formation. The dichotomic divisions of the mesenteric artery together with the so-called primary arcades surround an area considered more or less avascular.

In certain sections of the colon the main or primary arcades form secondary arcades of the second, third and fourth order. They are found in the pelvic section of the colon regularly and with lesser frequency in the splenic and hepatic flexures they may also be found in the ascending transverse and descending colon. The terminal portions of the primary arcades together with the secondary arcades form so-called "Dwyer" parallel blood vessels, which have a course parallel to the intestinal axis. From them the long and short vasa recta originate.

The purpose of the arcades is to maintain the blood supply to all parts of the intestine in cases in which

there may be an interference with the blood supply to certain portions, as from impacted fecal matter paralytic ileus trauma torsion or mesenteric thrombosis.

Similar arcades can be found in only a few other places in the body such as the palm of the hand, junction of the nasal and facial arteries, intercostal regions, circle of Willis, and junction of the cerebrum with the spinal medulla.

The purpose of the arcades is twofold (1) maintenance of the blood supply and (2) maintenance of adequate blood pressure according to hemodynamic laws.

The presence of arcades counteracts the possible marked diminution of pressure at terminal ends of the blood vessels which might lead to nutritional and functional disturbances.

ARTHUR F. CIPOLLA, M.D.

One-Stage Resection and Anastomosis of the Colon
J. WILLIAM HINTON AND S. ARTHUR LOCALIO. *Ann. Surg.*, 1948, 127 12

One-stage resection of the colon without proximal colostomy is a safe procedure for nonobstructing lesions. The mortality morbidity and hospital stay are reduced. Careful preoperative preparation and attention to details of operative and postoperative treatment are essential for success. Aseptic anastomosis with the Furness clamp is a satisfactory and simple method.

The authors report a series of 26 consecutive colonic resections, covering all regions of the colon above the peritoneal reflection. They were done in one stage without a proximal colostomy or ileostomy and with septic anastomosis by means of the Furness clamp. The mortality was 3.8 per cent.

CHARLES BARON, M.D.

Rectosigmoid Cancer and Carcinoma of the Distal Sigmoid. Resection and Primary Anastomosis (Cáncer rectosigmoideo y de la porción distal del sigmoideo. Resección y enteranastomosis primaria). ARCEL N. CÁRMONICO. *Prensa méd. argent.* 1947 34 2319.

The operation of segmentary resection and primary enteranastomosis for treatment of cancer of the rectosigmoid and the distal portion of the ilio-pelvic colon gives satisfactory results.

This procedure justifies its election over abdominopelvic resection for the following reasons (1) there is only moderate mutilation of the normal anatomy, (2) the mortality is relatively lower (3) the anorectal sphincter is preserved (4) the normal intestinal pathway is re-established (5) complications involving the genital and urinary organs which occasionally are seen in abdominopelvic resections, are avoided (6) the period of hospitalization is shortened and (7) the patient is rehabilitated both physically and psychically.

The author presents 3 clinical cases of tumors of the sigmoid and rectosigmoid in which a primary enteranastomosis was done. In 2 of the 3 cases the

the aliment and makes available a more flexible and effective approach to them.

Fifteen Years Experience with Free Feeding of Patients with Bleeding Peptic Ulcer; Fatal Cases. E. MEULENGRACHT *Arch. Int. M.* 1947 80: 697

Fifteen years ago Meulengracht introduced the 'free feeding' program in the treatment of bleeding peptic ulcer or gross hemorrhage with hematemesis and melena. This article deals with the results of 15 years of systematic use of free feeding.

The treatment consists of prompt and frequent feedings. From the first day after admission to the hospital the patients are given a full 'puree' diet. It was rather at random that the puree diet was chosen. Any other form of bland and nonirritating diet based on the culinary customs of the particular locality will do as well. Adherence to the principle of something to eat and drink from the first day and a varied and liberal diet given in frequent meals is the important factor.

A total of 1,031 patients with bleeding gastric ulcer were treated according to these principles. The material comprises only patients with gross hemorrhage i.e., distinct hematemesis or directly visible melena. Of the 1,031 cases, 26 terminated fatally during the patient's stay in the hospital. If all the fatal cases are included, the gross mortality was 2.5 per cent. If cases in which death was clearly or mainly due to causes other than bleeding are excluded, as well as those in which the patients died 24 hours after admission to the hospital and therefore before they had received the treatment, the net mortality was 1.5 per cent.

Relative to surgery the viewpoint given was that a patient with bleeding gastric ulcer should not be transferred for operation during or just after a hemorrhage, and a review of the fatal cases rather serves to strengthen this opinion even if there might be a few cases in which operation might be lifesaving. As shown by the fatal cases, operation may be considered when the patient is more than 40 years of age, and has persistent or repeated bleeding which manifests itself as hematemesis and threatens life in spite of repeated blood transfusions. There should be no serious contraindications to operation, the presence of an ulcer should have been proved by roentgenologic study and a good surgeon should be available.

STEPHEN A. ZEEMAN, M.D.

A Study of the Results, both Favorable and Unfavorable, of Section of the Vagus Nerves in the Treatment of Peptic Ulcer. WALTER WALTERS, HAROLD A. NEERLING, WILLIAM F. BRADLEY, JOHN T. SMALL, and JAMES W. WILSON. *Ann. Surg.* 1947 26: 679.

The authors' studies on section of the vagus nerves indicate that the results are inconsistent, variable, and in most cases, unpredictable. The pain relief obtained is probably brought about by the release

of gastrospasm and the reduction of gastric acidity as a result of the interruption of cephalic stimulation, and other factors not now understood. The expense of this is dilatation of the stomach with frequent troublesome retention of gastric secretion and, in some cases, food remnants. Moreover that relief of pain is not the result of healing of the ulcer must be considered, since in one of the cases observed an unsuspected acute perforation of duodenal ulcer developed.

Reduction in gastric acidity and disturbances of motility of the stomach and small intestine are of frequent occurrence after operation. In some cases such disturbances are temporary and in others they are prolonged, persistent, and troublesome. In such cases patients have complained of frequent belching of foul-smelling gas, a sensation of fullness and bloating after meals, and, in a few cases, nausea and diarrhea.

There have been 3 deaths in the hospital in the 83 cases observed; 2 of these could be attributed directly to cardiovascular accidents and one patient died of an unsuspected perforated duodenal ulcer with a subdiaphragmatic abscess. Gastroenterostomy had been done in association with gastric neurotomy.

In evaluating the results of the operation, it must be proved that an ulcer is present and that the vagus nerves have been completely sectioned. The authors' opinion is that the best approach is by means of a transabdominal incision for such an approach allows both examination of the ulcer and exploration of the gastrointestinal tract and performance of such procedures as might seem necessary to supplement gastric neurotomy. The greatest field of usefulness for gastric neurotomy seems to be in the treatment of ulcers after partial gastrectomy and in certain cases of nonobstructive duodenal ulcers in which the cephalic phase of gastric secretion is marked and pain is intractable. If the operation is used in the treatment of gastrojejunal ulceration after gastroenterostomy the possibility of obstruction at the stoma and at the site of the healed or reactivated duodenal ulcer must be considered.

In view of the inherent ability of the gastrointestinal tract to regain through anatomic and compensatory mechanisms its function after operative procedures which disturb neuromuscular continuity and since restoration of gastric acidity and gastric motility has occurred within a two year period in dogs in which gastric neurotomy has been performed, the possibility of such a return in human beings must be kept in mind constantly.

For the time being, the operation of gastric neurotomy must be considered to be in the investigative stage and the effects of the operation carefully studied.

Obstruction of the Duodenum with Special Reference to Gallstone Perforations. JOHN HARTZ. *Acta chir. scand.* 1947 96: 33.

Cases of duodenal obstruction although reported from time to time, are still of considerable interest.

From an etiological standpoint the stenosis may be caused by congenital anomalies as well as by acquired intraduodenal or extraduodenal diseases.

According to some writers the duodenum is normally slightly compressed and narrowed under the root of the mesentery and consequently a tendency to obstruction will result if the lumen is further diminished.

The author mentions the congenital causes of duodenal obstruction and refers to their types and mechanism.

Among the acquired causes of duodenal obstruction apart from tumors mention should be made of gallstones which have perforated to the duodenum and subsequently impacted themselves either in the superior part of the duodenum or at the duodenojejunal flexure and produced a total or partial obstruction there. Apart from the choledochus the calculi most frequently leave the bile ducts through perforations of the duodenum, next through the colon, and finally through other organs.

In other instances the calculi were not in themselves large enough to obstruct the lumen, however they caused such an inflammatory hyperplasia of the pylorus as to obstruct the passage.

The author has had the opportunity to observe 3 cases of duodenal stenosis 2 of which are reported.

Only a few cases of gallstones as the direct cause of obstruction of the duodenum are reported in the literature, and the author has therefore deemed it appropriate to recapitulate briefly the cases which he has succeeded in tracing in the literature.

It is seldom possible to map out the very choledochoduodenal passage. When symptoms have been present they have taken the form of intensive stabbing pain thus resembling initially a perforation.

A brief account is given of the relation between megaduodenum and ulcer. HARRY W. FINE, M.D.

Study of the Vascularization of the Colon and the Anastomotic Arcades (Contributo allo studio della vascolarizzazione del colon le arcate anastomotiche). ANDREA BERTOCCHI *Chirurgia*, 1947 2 105

The collateral vascularization of the mesenteric artery is of two types (1) dichotomic or consisting of two branches, and (2) in arcade formation. The dichotomic divisions of the mesenteric artery together with the so-called primary arcades surround an area considered more or less avascular.

In certain sections of the colon the main or primary arcades form secondary arcades of the second, third and fourth order. They are found in the pelvic section of the colon regularly and with lesser frequency in the splenic and hepatic flexures they may also be found in the ascending transverse and descending colon. The terminal portions of the primary arcades together with the secondary arcades form so-called "Dwyer" parallel blood vessels, which have a course parallel to the intestinal axis. From them the long and short vasa recta originate.

The purpose of the arcades is to maintain the blood supply to all parts of the intestine in cases in which

there may be an interference with the blood supply to certain portions, as from impacted fecal matter, paralytic ileus, trauma, torsion or mesenteric thrombosis.

Similar arcades can be found in only a few other places in the body such as the palm of the hand, junction of the nasal and facial arteries, intercostal regions, circle of Willis, and junction of the cerebrum with the spinal medulla.

The purpose of the arcades is twofold (1) maintenance of the blood supply and (2) maintenance of adequate blood pressure according to hemodynamic laws.

The presence of arcades counteracts the possible marked diminution of pressure at terminal ends of the blood vessels which might lead to nutritional and functional disturbances.

One-Stage Resection and Anastomosis of the Colon J. WILLIAM HINTON and S. ARTHUR LOCALIO *Ann. Surg.*, 1948, 127 12

One-stage resection of the colon without proximal colostomy is a safe procedure for nonobstructing lesions. The mortality, morbidity and hospital stay are reduced. Careful preoperative preparation and attention to details of operative and postoperative treatment are essential for success. Aseptic anastomosis with the Furniss clamp is a satisfactory and simple method.

The authors report a series of 26 consecutive colon resections, covering all regions of the colon above the peritoneal reflection. They were done in one stage without a proximal colostomy or ileostomy and with septic anastomosis by means of the Furniss clamp. The mortality was 3.8 per cent.

CHARLES BARON, M.D.

Rectosigmoid Cancer and Carcinoma of the Distal Sigmoid. Resection and Primary Anastomosis (Cáncer rectosigmoideo y de la porción distal del sigmoideo. Resección y enteranastomosis primaria). ABEL N. CANÓDICO *Prensa med. argen.* 1947 34 2319.

The operation of segmentary resection and primary enteranastomosis for treatment of cancer of the rectosigmoid and the distal portion of the ilio-pelvic colon gives satisfactory results.

This procedure justifies its election over abdominoperineal resection for the following reasons (1) there is only moderate mutilation of the normal anatomy, (2) the mortality is relatively lower (3) the anorectal sphincter is preserved (4) the normal intestinal pathway is re-established (5) complications involving the genital and urinary organs, which occasionally are seen in abdominoperineal resections, are avoided (6) the period of hospitalization is shortened and (7) the patient is rehabilitated both physically and psychically.

The author presents 3 clinical cases of tumors of the sigmoid and rectosigmoid in which a primary enteranastomosis was done. In 2 of the 3 cases the

author practiced a transverse colostomy, and in the third case he made a cecostomy as an adjunct to the resection and enterostomosis.

Great importance must be placed on the following rules in preparing the patient for surgery (1) the bowel residue must be decreased (2) the serum protein should be at least 6.5 gm. per cent, (3) good intestinal drainage must be maintained, (4) the blood picture should be normal and (5) the intestinal bacteria must be combated with sulfasuxidine and sulfathalidine.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Studies of Responses to Certain Hepatic Tests in Diseases of the Liver and Biliary Tract. Serum Cephalin Cholesterol Flocculation, Thymol Turbidity Thymol Flocculation and Colloidal Gold Responses. JOHN R. NEFF, P. REID BARRETT and JOHN G. REINHOLD. *Gastroenterology* 1947 9: 656.

Analysis of the responses of the cephalin cholesterol flocculation, thymol turbidity thymol flocculation, and colloidal gold tests in various diseases of the liver and biliary tract revealed that none offered a reliable means of differentiating between jaundice due primarily to extrahepatic bile duct obstruction and that due to intrahepatic causes unrelated to extrahepatic bile duct obstruction.

The diagnostic value of the individual flocculation test varies with the disease concerned and with the purpose for which it is used (in the detection of liver disturbance or in differential diagnosis). At least in the initial study of hepatic and biliary tract disease the use of all of these tests as a group offers more information than the use of any one or two of them. If only two tests are used the cephalin cholesterol flocculation and thymol reactions are preferred. No one test of this group is reliable for "screening" or for aid in differential diagnosis.

WALTER H. NADLER, M.D.

Clinical, Radiomanometric, and Therapeutic Study of Valvular Gall Bladders. A Purely Mechanical Form of Intersectocystic Dykinesia. (Étude clinique radiomanométrique et thérapeutique des vésicules à soupape. D'une variété mécanique pure de dykinesia intersectocystique.) J. CASOLI, J. HOFF and M. MICHAMON. *Rev. chir. Par.* 1947 66: 207.

Radiomanometric studies have revealed the valvular sphincter mechanism at the neck of the gall bladder to be just as important as that of the choledochoduodenal junction in the causation of biliary dyskinesia. The gall bladder in these cases is anatomically and histologically normal. Also cholecystography and the administration of fatty meals show normal conditions. Nevertheless, the symptoms may be of long duration. The condition is one of pure dyskinesia and dystonia. Stenotic cystitis can be excluded and there is no spasmodic occlusion of the vesical sphincter. Radiomanometry reveals a purely

Fig. 2. Schmieden's schematic presentation of valvular obstruction of the neck of the gall bladder

mechanical disturbance of the valve mechanism caused by an apparently constitutional anomaly of the neck of the gall bladder. Schmieden was the first to draw attention to this anomaly (Fig. 2).

Biliary dyskinesia causes a very painful type of gall bladder hitherto not considered pathologic. Three cases are described in detail.

The paroxysms of pain are not as acute as in lithiasis but are definitely biliary in character with typical radiations and respiratory inhibition. There is no fever, but the pains recur incessantly at irregular intervals related or not, to the ingestion of food. This condition may persist for years, often beginning in adolescence. Associated reflex symptoms include vomiting, nausea, and gastric heaviness, and the general condition is always affected. There is a history of failure of medical treatment, and the patient finally presents a nervous state, frequently mistaken for a psychopathic affection.

X-ray examinations and intubations yield negative results. The motor function is preserved with an apparently paradoxical Graham-Boyd test. The only clinical sign is induced pain. Pressure in the region of the gall bladder causes a pain exactly like that experienced in the attacks. Cholecystostomy under radiomanometric control is indicated to disclose the source of the pain. Vesical decompression relieves the pain immediately. As the result of drainage, alimentation is facilitated and the general condition improves.

Radiomanometry during cholecystostomy shows a normal sensibility threshold but increased intravesical pressure causes pain exactly like that in the attacks. With decompression the pain disappears. These gall bladders usually fill at very low pressures (from 25 to 35 cm.). The valve effect is demonstrated by the contrast between the facility of exit of bile through the tube and the complete or incomplete obstruction of the contrast medium through the cystic valvular sphincter. A comparative analysis of radiomanometric studies of the valvular mechanism in the fasting state and following a fatty meal was made. To the astonishment of the authors, the fatty meal suppressed the obstruction in the neck of the gall bladder. The hormone cycle did not affect this condition. The cystic duct remained obstructed in

Fig. 2. (Caroli *et al*) Inclination of the cystic duct at its site of origin explaining obstruction due to kinking during distention of the neck of the gall bladder

the fasting state and permeable following a fatty meal. It was demonstrated that partial or complete obstruction in the fasting state was caused by distention of the neck of the gall bladder from below upward. Such distention takes place following even very moderate increase in intravesical pressure under radiomanometric control. The films show clearly that distention of the neck of the gall bladder leads to kinking by compression near the origin of the cystic duct. This obstacle makes the cystic duct and choledochus appear very small. The block is immediately released on the ingestion of fat. Ten minutes after such a meal, the gall bladder begins to diminish not only in width but in height. The vertical retraction of the major axis of the gall bladder forces downward the site of implantation of the cystic duct and straightens out the proximal kink when present and the lumen of the excretory canal is placed in alignment with the gall bladder cavity. The bile then escapes freely and the cystic duct appears to be normally filled.

The roentgenogram shows a pear-shaped gall bladder, because of incomplete differentiation of the neck and aplasia of its valves. This arrested development of the vesical neck is regarded as one of the causes of intracholecystic obstruction (Figs. 2 and 3).

Thus distention of the neck of the gall bladder may cause compression and occlusion of the cystic duct, whereas reduction of the major axis of the gall bladder by a fatty meal corrects the angulation and places the canal in a vertical position in prolongation of the vesical axis.

Fig. 3. (Caroli *et al*) Kinking of the cystic duct and valve at its site of origin

This condition is very different from that known as functional hypertrophy of the sphincter of Lutkens. Antispasmodics gave no relief. A differential diagnosis must be made from sclerosing cystitis. A type to be discussed in a future article is that in which kinking is due to atony of the gall bladder at the junction of the infundibulum and neck of the gall bladder. This might be designated as interfundibulocholecystic dyskinesia. The mechanism is similar to that described.

The good results obtained by administration of olive oil in some cases of biliary disturbance may be ascribed to the effect of fat in the conditions described. However in severe cases such treatment would be futile, for it would be too difficult to hinder painful refilling of the gall bladder day or night. In mild cases cholecystostomy may afford lasting relief. However in most cases cholecystostomy is only an initial stage permitting exploration of the bile tract. In two-stage operations there is always the risk of the development of adhesions. The diagnosis should be verified before cholecystectomy is done. The second stage consists of choleduodenostomy or cholecystectomy with a slight preference for the latter. Internal manipulations carry the added risk of biliary infection whereas cholecystectomy yields lasting benefit.

EDITH SCHAWCHKE MOORE.

Biliary Dystonias (Les dystonias biliaires) F. POUILLON and R. GUILLER *J. chir., Par.*, 1947 63 550.

In defining biliary dystonia, the authors emphasize the fact that this is a general and complex term including all changes of tonus in the bile tract. They wish to eliminate from their discussion in the present article all cases of secondary dystonia. In other words all cases associated with some macroscopic obstacle to evacuation. Only primary dystonias, of whatever etiology are included. Since the strictly vesicular dystonias have been well known since the work of Chiray and Pavel and because the new diagnostic procedure of radiomanometry permits a better understanding of the function of the biliary sphincters and of the excretory ducts, and may explain certain hitherto obscure clinical manifestations the present

article will be devoted to a pathologic study of the excretory channels and their sphincter apparatus.

Strictly speaking, the term *dyskinesia*, frequently used interchangeably with *dystonia*, pertains to conditions related to a disturbance in the motor function of the biliary passages without any change in the state of the muscles. In practice the two conditions are frequently associated or consecutive to one another.

Under the designation *biliary dystonia*, the authors will therefore discuss all functional conditions affecting the motor function of the excretory passages and the changes in function of their sphincter apparatus. In this study very special emphasis is placed on the value of radiomanometry as recommended by Caroli in 1941.

More recently Mallet Guy introduced the graphic registration of curves of biliary pressure which, besides affording purely numerical findings, shows the mode of reaction of the muscles of the gall bladder and choledochus to hyperpressure tests. Finally in 1942 he described a method of interoperative functional exploration yielding important information to guide the surgeon in his choice of treatment for a given functional disturbance. It is needless to state that to obtain valid results with these new methods, the exact technique described by their authors must be followed.

Emile SCHWARTZ MOORE.

Dystonias of the Gall Bladder (*Dystonies du systéme vésiculaire*). F. POILLIOT and GUY ALBOT. *J. chir. Par.* 947 63 558.

Radiomanometry of the biliary tract, pharmacodynamic tests and physiologic stimuli have demonstrated in man the existence of a sphincteric neuromuscular mechanism at the level of the neck of the gall bladder. This sphincter has greater contractile force than that of the sphincter of the choledochus. It varies individually and offers an explanation for certain constitutional morbid predispositions.

When the bile coming from the liver attains a certain pressure between the sphincter of Oddi and the vesicular sphincter the sphincter relaxes and the gall bladder fills. This filling can be hindered by morphine or the ingestion of fat. In evacuation of the gall bladder, this valve acts as a dam to keep pressure in the gall bladder from increasing the intracholedochus pressure. At the level of this sphincter there is a double, intrinsic and extrinsic innervation, the former playing a part similar to that of the Auerbach plexus in the intestine and the latter connecting this region with the general innervation. Any mechanical change, inflammatory lesion, or nervous disturbance in this neck of the gall bladder may give rise to serious functional disturbances of the gall bladder. The various vesicular dystonias of apparently primary type may be caused by (1) anatomic anomalies of the bile tract, (2) even slight local inflammatory changes, or (3) dysfunction of vesicular motility or of the cystic valvular sphincter apparatus.

Experimental and clinical findings point to the sympathetic system as an etiological factor in bill-

aryn dystonia, and therefore treatment should be directed toward its regulation.

Clinically hypotonia of the sphincter of Lutter resembles atony of the gall bladder but it causes less severe symptoms. Clinical examination yields negative results. Only the Murphy maneuver occasionally induces pain. Duodenal drainage yields an abundance of B bile, and is usually followed by improvement, especially of the migraine. Cholecystography confirms atony of the gall bladder. Radiomanometric findings are usually normal. The tonicity of the gall bladder is difficult to demonstrate by postoperative radiomanometry in a drained gall bladder. Occasionally the cystic pressure is low while the pressure at the sphincter of Oddi is normal. There are also formes frustes and atypical cases. Radiomanometry reveals only the low pressure required for filling the gall bladder and sphincter function, with functional integrity of the rest of the tract.

Cystic hypertension was first described by the author in 1944. In this condition there are acute attacks of pain in the subhepatic region, which may simulate hepatic colic, coming on after dietary indiscretions or emotional upsets. Or there may be only vague pain in the right subcostal region with heaviness in the epigastrium, or attacks of severe pain in the right iliac fossa with intestinal symptoms leading to futile appendectomy. Radiomanometric tests alone will reveal this condition.

Radiomanometric tests have shown that the gall bladder fills at a water pressure of from 15 to 30 cm., but the cystic canal yields only to higher pressures and may resist even 40 or 50 cm. of water pressure. Vasodilating drugs will overcome this resistance only temporarily. Cystic hypertension is occasionally accompanied by milder pain in the region of the sphincter of Oddi or may be associated with a mild cholecystitis or cholelithiasis. Here the purely functional disturbance may be the cause of the other two conditions.

Radiomanometric pressure tests have shown a pain threshold of induced pain which is constant in each individual and occurs normally between a water pressure of 30 and 40 cm., but never below 20 cm. The margin between the pressure required for transit of bile and the pain threshold is usually 10 cm. Some pain syndromes may be due to a drop in this threshold of sensibility which is caused by increased resistance of the sphincter of Oddi or by a lowering of the induced pain threshold, the pressures for transit through the sphincters remaining normal. This is the syndrome known as biliary hyperesthesia and occasionally associated with hyperesthesia of the urinary tract. It suggests a systemic dysesthesia. There are, of course, all degrees of hypotension or hypertension and frequently the milder forms are not strictly localized, or associated, as mentioned above, with other pathologic conditions of the biliary tract.

As regards the treatment of dystonias of the biliary tract, a proper evaluation of results is, of course, possible only in radiomanometrically controlled cases of recent observation. In older cases with uncertain

indicate the need for more extensive gastrectomy or vagotomy as part of the procedure.

The results observed in these animals, although disheartening, are yet promising enough to warrant further investigation. The most important factors in successful instances seem to have been careful surgical technique, adequate whole blood transfusion during operation, and careful postoperative care.

JOHN J. MALONEY, M.D.

Two Cases of Traumatic Rupture of the Normal Spleen (Su due casi di rottura traumatica di milza normale) MARIO BALLESTRERO. *Boll. Mem. Soc. piemontese chir.* 1947 7 439.

Traumatic lesions of the spleen may be divided into contusions, ruptures, wounds and hernias. Ruptures represent from 70 to 85 per cent of all the traumatic lesions of a normal spleen. They may be of two types: spontaneous, i.e. without evidence of external trauma, and traumatic in the strict sense of the word.

In descending order of frequency ruptures of the spleen are combined with rib fractures and injuries of the kidneys, lungs, stomach, liver, pancreas or colon.

A sharp distinction between a contusion and a rupture of the spleen cannot always be made. The following types of injuries may however be distinguished in the majority of cases: (1) subserous ecchymoses, (2) subcapsular or intraparenchymal hematomas, (3) simple rupture of the capsule, (4) multiple lacerations, and (5) cracks through the organ.

The author reports 2 cases of traumatic rupture of the spleen: one in a 16 year old boy, following a collision of a motorcycle which he was riding with an automobile, and the other in a 13 year old boy following a blow against the left hypogastrium.

The author draws the following conclusions from his observations: A traumatic rupture of a normal

spleen is rarely recognized, chiefly because of a lack of typical symptomatology. The latent period between the initial injury and the secondary hemorrhage which produces hemoperitoneum is the most important sign. In one of the author's cases the latent period lasted 30 hours.

A postoperative hyperthermia following the splenectomy is the most important complication. One of the author's patients developed a post-traumatic pleurisy but both of his patients recovered.

Due to the vicarious function of other organs, absence of the spleen is usually well tolerated by the patient, but he should be advised to limit his physical activities such as heavy sports.

JOSEPH K. NARAT, M.D.

The Value of Splenectomy in Certain Splenic Syndromes in Children (Considerazioni sulle splenectomie in alcune sindromi spleniche infantili). VITO TORIO FERRERO, PIERO FORMARA, CARLO ALDO SCHIAVINI. *Boll. Mem. Soc. piemontese chir.* 1947 17 451.

Splenectomy, which as a rule is better tolerated by children than by adults, was employed by the authors in 3 children suffering from Cooley's disease, or Mediterranean anemia. The effect on erythroblastosis was very pronounced in 2 cases as the number of nucleated red cells rose markedly. In the third case the curve was erratic. However the operation did not exert any permanent beneficial effect on the patients.

In 2 cases of the sclerocongestive syndrome, or Banti's disease, the results of splenectomy were not definite. In 1 instance an intensive gastrointestinal hemorrhage occurred 3 1/2 years after the operation.

On one patient with Werthof's disease splenectomy produced a beneficial effect. On the other hand in a patient with an atypical thrombopenic syndrome the results of the operation were dubious.

JOSEPH K. NARAT, M.D.

GYNECOLOGY

UTERUS

Endometritis Tuberculosa. RINGER ERIKSEN *Acta obst. gyn. scand.*, 1947 37: 249.

The author presents a superficial review of the literature concerning endometrial tuberculosis. The incidence pathogenesis diagnosis, and treatment are stressed.

He then presents 38 cases of tuberculous endometritis in patients treated in 40 Danish hospitals during the years from 1931 to 1940. The diagnosis in all of the cases was established by histological examination of the curettings. In no case was the condition suspected in advance. In 2 cases the diagnosis was corroborated bacteriologically once by culture and once by guinea pig inoculation of the uterine secretion or curettings. In all these cases the disease was apparently limited to the uterus and exploration revealed no signs of disorders of the adnexa. In 3 cases salpingography showed normal conditions.

This group of 38 patients constitutes 15 per cent of all cases of gynecological tuberculosis verified histologically which were reported from these same hospitals for the same period from 1931 to 1940. In the author's review of the literature one notes that tuberculosis localized exclusively to the endometrium represents about 10 per cent of the cases of genital tuberculosis found in postmortem examinations of adult women. However this reported incidence varies with the investigator from 1.77 to 28.6 per cent and as in the author's series exclusion of adnexal disease was not always absolutely certain.

The ages in this series ranged from 16 to 58 years with an almost equal distribution among the four decades from 20 to 60. In 36.8 per cent of the cases there was a history of tuberculosis elsewhere in the body. Among the married women there was an incidence of sterility of 53.3 per cent.

The predominant symptom which led patients to seek medical attention was metrorrhagia, which occurred in 44.7 per cent of the cases. Other complaints were vaginal discharge of an offensive odor in 23.7 per cent, sterility in 13.5 per cent, dysmenorrhea in 10.5 per cent, abdominal pain in 7.9 per cent, and postmenopausal bleeding in 7.9 per cent. Menorrhagia, amenorrhea, and lumbar pain also occurred.

The treatment of the 38 patients was varied. In addition to the curettage which was performed on all patients, 3 patients were subjected to hysterectomy, 3 were treated by roentgen irradiation, and 13 were treated with the carbon arc lamp. Only one of the hysterectomies was performed for the tuberculosis alone. One of the patients had, in addition, a prolapsing uterine polyp and another had a fibroid.

In 1935 all but 3 patients were followed up. More than half of them were examined. Twelve patients or 31.6 per cent complained or had complained of genital symptoms. Six or 15.8 per cent, developed

tuberculous salpingitis. In 2 of these the salpingitis occurred within a few weeks after the original diagnostic curettage. Two others of these 12 patients died, one of tuberculosis of the spleen and the other of tuberculosis of the adrenal glands. The tuberculous endometritis recurred with certainty in 5 cases or 13.2 per cent.

Of the 23 patients, or 60.5 per cent, who had no pelvic symptoms or signs following the original curettage, 4 developed tuberculosis in other organs which led to a fatal result in 3. A repeated curettage in 1 patient after 4 months, in 1 patient after 2 years, and in 1 patient after 5 years showed no tuberculosis. On the other hand, a repeated curettage in 8 other patients over varying periods of time showed the continued presence of the disease.

Two patients in this series gave birth to normal children and had a normal puerperium. The author discusses the relationship between pregnancy and endometrial tuberculosis in connection with these 2 cases and with 8 other similar cases from the literature.

L. JAMES TALBOT M.D.

Fibrosis Uteri. R. SOOMAKER AND J. E. KAMLER. *Arch. Path. Chic.* 1947 44: 633.

The criteria for the diagnosis of fibrosis uteri have never been clearly defined from either a clinical or a pathological standpoint. Many clinicians and pathologists deny the existence of the entity. The term was frequently used in reference to the asymmetrically and slightly enlarged uterus to which gross pathology could be noted and with a history of bleeding. The authors in this study made an attempt to determine whether the disease is a clinical entity or not, and to define the pathological criteria for making a diagnosis.

They identified four layers in the uterine wall: (1) the submucosa, (2) the vascular, (3) the supravascular, and (4) the subserosa. The dividing lines between them are indistinct. Among the 245 uteri studied, 27 cases of fibrosis uteri were diagnosed. All but 2 of the patients complained of profuse bleeding at the time of menstruation. None of the patients had prolonged bleeding. In more than half of the patients additional lesions were found. In all but one case the uterus was enlarged.

In fibrosis uteri one notes an abnormal amount of connective tissue occurring both between the muscle bundles and more characteristically around the individual muscle cells. This increase is due to an increase in the collagen fibers and not in elastic fibers or reticulum. It is significant that there is a greater percentage of fibrosis in the submucous layer than in the other layers.

Typically the patient gives a history of profuse menorrhagia without metrorrhagia and usually without dysmenorrhea. The uterus is typically symmetrically enlarged. The myometrium is pale

cent in group IV with 5 year cures. Groups I and II combined had a 5 year survival rate of 43.2 per cent and groups III and IV one of 13.9 per cent. It is thus evident that radiation therapy is approximately three times more effective in the earlier than in the later stages of the disease.

The author also analyzed the cases without 5 year survival after treatment. A total of 296 patients (54.7%) died in the first year after irradiation and 454 (83.9%) died within the first 2 years. Primary mortality from the therapy occurred in 39 patients (4.6%) classified from groups I to IV inclusive, 2, 10, 16 and 11 patients were in groups I, II, III and IV respectively. Death ensued from thrombophlebitis and embolism in 10 cases, hemorrhage in 1 case, cerebral hemorrhage in 1 case, cardiac paralysis in 2 cases, pneumonia in 2 cases, peritonitis in 18 cases, sepsis in 4 cases, uremia in 3 cases and unknown causes in 3 cases.

Although there were fewer cases of adenocarcinoma (55) than squamous cell carcinoma (731) the former seemed to respond better to irradiation since only 101 (27.5%) of those with squamous cell carcinoma lived more than 5 years while 22 (40%) of those with adenocarcinoma survived for the same period of time.

PATIENTS TREATED BY SURGERY

Within the 10 year period 110 patients with cervical malignancy received operative treatment.

About one-half (58) received preoperative radium (33 in group I, 24 in group II, 1 in group III). Thirty six (63.1%) survived 5 years. The average radium dose was 3,344 mgm. hr., but for group II the dose was less (2,770 mgm. hr.). The higher preoperative radium doses did not appear to increase the percentage of recovery. Operation is best performed about 6 weeks after the radium application.

Fifty-one of the 110 patients subjected to operation received no radium before surgery (40 in group I, 8 in group II, and 3 in group III). 31 (62.7%) lived 5 years. The following operations (with recovery rates) were performed: complete hysterectomy with bilateral salpingo-oophorectomy in 21 cases (47.8%), Wertheim operation in 63 cases (66.7%) and vaginal hysterectomy in 22 cases (72.7%). Four patients (3.6%) died primarily 2 after each of the abdominal procedures.

Although at present the trend is toward irradiation therapy the author believes that certain patients in group I should be treated surgically. Better results are attained in patients belonging to group II if radium is used preoperatively.

With postoperative recurrence prognosis is very poor.

ALL PATIENTS LIVING 5 YEARS

Of the 931 patients with cervical carcinoma, 263 (28.2%) lived longer than 5 years. Subdivided according to groups 61.8 per cent of those in group I, 42.3 per cent in group II, 19.9 per cent in group III and 3.6 per cent in group IV recovered.

The percentage of recovery rose perceptibly from 1937 on. This the author attributes to the greater

number of lesions seen earlier. It is highly desirable to treat as many patients as possible while they are in Group I, but results are so favorable in those of group II that if they belong to either group I or II 48.7 per cent or almost half can be cured.

Anticoagulation Therapy with Heparin/Pitkin Menstruum in Thromboembolic Disease Complicating the Puerperium and Gynecologic Surgery. HARRY J. GREENE and LEO LOEWY. *Am J Obst.*, 1947 54 958.

The clinical department of heparin/Pitkin menstruum has been observed in 53 patients representing all forms of venous thromboembolic disease encountered in obstetrical and gynecologic practice.

The authors present in detail their formulae, dosage plan, method of administration and the Lee-White modification of Howell's method for the determination of blood coagulation time used in following the patient's clinical course.

The disadvantages, complications and efficacy of other methods of treatment are compared to the use of heparin/Pitkin. These methods are the conservative medical treatment, surgical approach and anticoagulant therapy with dicumarol.

The span of treatment proposed for uncomplicated thrombophlebitis or phlebotrombosis (or both) was 10 days to 2 weeks. For patients with pulmonary embolization an additional week or two of therapy was required depending upon the extent of pulmonary infarction. In any event, the full effect of the heparin was present when the patient was first allowed out of bed.

The results in this series were satisfactory as judged by effective control of pulmonary embolization, marked amelioration of pain and discomfort, rapid recession of edema, reduction in morbidity, acceleration in convalescence, and virtual absence of residual edema, particularly when patients were treated without delay.

Most informative are the statistics with respect to the patients who had pulmonary embolization. There were 18 patients in this group with but one fatality representing 1.8 per cent of the entire series. The causative factors responsible for the one treatment failure have been analyzed.

As a result of observations of its clinical department, the subcutaneous administration of heparin in the Pitkin menstruum is recommended as a safe, simple, practical and effective method for anticoagulation therapy in thromboembolic disease complicating the puerperium and gynecologic surgery.

JOHN R. WOLFF, M.D.

Precursors of Corpus Carcinoma Estrogens and Adenomatous Hyperplasia. S. B. GUNBERG. *Am J Obst.* 1947 54 903.

A pattern of adenomatous hyperplasia of the endometrium is described which bears a constant rela-

tion to estrogen stimulation in both benign and malignant tissues. The author presents data concerning this endocrine tumor relationship in four related groups.

1 *Response of the human endometrium to granulosa cell tumor of the ovary.* The finding of hyperplasia of the endometrium in patients harboring such an ovarian tumor is well known. Increasing reports in the literature and the author's personal experience show that a significant percentage of those patients responded with endometrial malignancy. A striking degree of hyperplasia was noted in many of the author's cases of functioning ovarian tumors, and in one patient the condition was associated with endometrial carcinoma. These hyperplastic endometria may be placed in a graded progression of activity which moves quite readily toward the malignant one suggestive of an estrogen-cancer relationship.

2 *Hyperplasia of the human endometrium following prolonged estrogen administration.* Twenty human endometria with advanced degrees of hyperplasia produced by prolonged estrogen administration were studied. While none could be called malignant, several endometria showed characteristics similar to those produced by the stimulus of granulosa cell tumor.

3 *Adenocarcinoma of the human endometrium following prolonged estrogen administration.* The author presents abstracts of 5 cases which are extremely suggestive of an etiologic relationship and the histologic data supporting them are also of a pattern which makes the suggestion strong enough to be significant, and certainly to warrant further study. In some areas one gains the impression that this pro-

cess is but an intensification of an atypical adenomatous pattern of hyperplasia. One can see typical cystic glandular hyperplasia, atypical (metaplastic) hyperplasia, and adenocarcinoma side by side in some sections. The multifocal malignant processes, often separated by areas of typical hyperplasia, present the picture of a generally stimulated tissue which has responded more intensely in some areas. There is a characteristic pattern which constantly recurs through these tissues. It is almost papillary in form. It shares morphologic properties with other tissues known to have been stimulated by estrogens. Also presented are abstracts of three other corpus carcinomas and an ovarian adenocarcinoma whose histories indicate their development may have been accelerated by estrogen administration and their histologic pattern modified.

4 *Relation of hyperplasia of the endometrium to the development of corpus carcinoma.* In an effort to evaluate the endocrine background of patients with corpus carcinoma, their reproductive histories were studied and deviations were noted which suggest abnormality of internal secretions: an increased incidence of infertility, delayed menopause, and menopausal bleeding. Thus, these individuals who apparently have an increased susceptibility to corpus carcinoma demonstrate a significant frequency of endocrine stigmas of a type which has been associated with infrequent ovulation and probably noncyclic persistent unopposed estrogen stimulation.

The well defined histologic pattern recurring in these related groups of tissues suggests that endogenous or exogenous estrogens play a role in the development of corpus carcinoma.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Face Presentation STEPHEN J. RUDOLPH, JR. *Am J Obst.*, 1947 54: 987

A series of 61 cases of face presentation occurring among 35 163 consecutive deliveries in the Philadelphia Lying In Hospital is analyzed in regard to etiology, management, and end results.

There was a high incidence of monstrosities: 5 of these were of the anencephalic type and 2 presented acraniorachischisis. In nearly 40 per cent of the cases the condition occurred in women with clinically normal pelvis who bore normal, average, or smaller than average infants and had no complications of etiological value. Of the 37 patients to whom etiologic factors were assigned 18 had abnormal pelvis and 12 had normal pelvis with large infants. There was one case of placenta previa, and one in which multiple turns of the cord occurred around the infant's neck.

There were no maternal deaths, but there were 12 fetal deaths, and only 4 of these occurred in babies who were normally formed and weighed more than 3 pounds. The death of 2 infants was due to poor obstetric judgment: one followed occult prolapse of the cord and one occurred antepartum; the cause unknown.

Delivery was spontaneous in 30 per cent of the cases; 25 per cent of the infants were delivered by forceps and by internal podalic version, and the remainder by cesarean section.

The author notes that the present trend is away from internal podalic version and breech extraction. With a decreasing maternal mortality and morbidity following cesarean section, the value of this procedure as a means of obtaining a living infant is increasing.

JOHN R. WOLFE, M.D.

LABOR AND ITS COMPLICATIONS

Local Anesthesia in Obstetrics ROBERT MACKAY *Med J Australia*, 1947 2: 595.

The author presents an excellent study on the use of local anesthesia in obstetrics. He introduces his subject with the comment that the technique described unlike other methods, has no effect on the unborn fetus. The time required for the introduction of the anesthetic is shortened by use of the Pitkin "Luer Lok" syringe connected to a small flask of 1.5 per cent solution of metycaine.

Two techniques are described: the first consisting of pudendal block, which is carried out in the following manner: a wheal is made on each side at the junction of the anterior two-thirds and the posterior one-third of each labium majus with a 22 gauge or 23 gauge needle; the labia are then infiltrated anteriorly up to the mons veneris and posteriorly and laterally down to the anus using the same wheals; a

long needle is then directed to the ischial spines, at which point 8 c.c. of the solution are injected. The levator ani are likewise injected, and a further injection is made slightly distal to the ischial tuberosity on each side.

The author describes three possible dangers—sepsis, intravenous injection, and the formation of hematomas—none of which he has as yet encountered. At the Women's Hospital Sydney Australia, local anesthesia is used routinely in patients with diabetes, cardiac disease, pulmonary disease, and severe pre-eclampsia. The fetal indications are prematurity and breech presentation. The clinical results have been remarkably good.

The technique of infiltrating the abdominal wall for cesarean section is carried out by making two skin wheals: one 2 cm. below the umbilicus and the other halfway to the symphysis. Subcutaneous injections are then made in a radial fashion from the two wheals. When the rectus sheath is exposed a needle is introduced beneath the anterior sheath and further injection is made. The fascia of the transversalis is likewise injected and at the same time, further injection in the retroperic area is carried out. After the peritoneum has been opened injections are made extraperitoneally. Frequently in the present series, sodium pentothal was used intravenously to supplement the local anesthesia. This was particularly necessary when the head was tightly wedged in the pelvic brim, and the clinical results were satisfactory. There was but one death that of a patient with mitral stenosis, due to cardiac failure 24 days after the operation.

Of 54 babies, 5 died. One of these was stillborn; one a premature infant who died of atelectasis; one died of erythroblastosis; and two died of anemia associated with placenta previa.

The author concludes that local anesthesia is safe for the mother and that it offers several advantages: namely, the reduction of postoperative complications (particularly a reduction in the occurrence of hemorrhage) and the excellent condition of the infants delivered.

JAMES F. DONNELLY, M.D.

Anesthesia in Labor and Cesarean Section CLIVE N. PATON *Med J Australia* 1947 2: 599

The author states that obstetric anesthesia is complicated by a number of basic factors: first that two individuals are subjected to the anesthetic agent and that the reaction of each may be different; second that regardless of the type of anesthetic, it is almost certain to interfere with the normal physiology of the labor; third that each of the three stages of labor call for a different type of anesthetic agent.

The discussion is divided into three main headings: namely, analgesia for the first stage of labor; anesthesia for the second stage; and anesthesia for operative obstetrics.

Nearly all of the known analgesic agents are discussed briefly their advantages and disadvantages being pointed out. In addition to his comments on the barbiturates, morphine, scopolamine, and demerol, the author mentions the use of trichlorethylene, which is self-administered by the patient from a specially designed semiautomatic inhaler. While not in common usage the technique of intravenous sodium pentothal drip analgesia is described. An interesting device was used to administer paraldehyde. This consisted of placing 17 minims of paraldehyde in capsules which were then frozen solid in a refrigerant and subsequently administered in this state to the patient. This eliminated the objection to the odor and taste of paraldehyde.

A wide variety of anesthetic agents for the second stage were described including chloroform, ether, nitrous oxide, low spinal, caudal and intravenous anesthesia. No clinical material was discussed.

In operative obstetrics particularly cesarean section, the anesthetist is faced with three major groups of patients. The first group consists of those patients who have obstructed labors but are otherwise in good health. The second group consists of patients who have medical complications such as cardiac disease, pulmonary disease, or toxemia, and the third group consists of those individuals who are either exhausted or who are in shock from blood loss or prolonged labor and infection.

Preoperative sedation was used in small amounts, the author's preference being morphine sulfate, gr. $\frac{1}{8}$ and atropine, gr. $\frac{1}{100}$. He expressed a preference for three types of anesthesia: cyclopropane, intravenous sodium pentothal with nitrous oxide and oxygen and spinal. All three have the advantage of minimal interference with the contraction of the uterus and very high concentrations of oxygen.

In conclusion, the author points out that no anesthetic has yet been found which is ideally suited for obstetric patients, and stresses the need of the psychological preparation of the pregnant woman for her labor and delivery. JAMES F. DOWDNEY, M.D.

Short Wave Therapy of the Pituitary Gland in Labor and in the Puerperium (La marconiterapia ipofisaria nel parto e nel puerperio). ENRIQUE GONZALEZ. *Ginec. obstet.* 1947 49: 1-3.

The author reports favorable results in 350 women in labor with either spontaneous or artificial rupture of the membranes following stimulation of the pituitary gland with short rays, and chemical and hormone therapy.

In simple uterine inertia, short wave therapy of the pituitary gland in conjunction with hormonal chemotherapy hastened the dilatation of the cervix and shortened the period of labor.

With this therapy in patients with placenta previa marginalis, following expulsion of the placenta, there was a physiological contraction and retraction of the uterus with less blood loss than was considered physiological and in all cases the third stage of labor occurred within 10 minutes.

In subinvolution of the uterus, stimulation of the pituitary gland favored contraction of the uterus and increased its tone.

The following technique was used: short waves having a length of 6 meters were applied through two electrodes in the temporal region. The first application was for 10 minutes but could be repeated in 4 hours.

Contraindications to this form of therapy are arterial hypertension, cardiac involvement, kidney pathology, retention edema, arteriosclerosis, syphilis, tuberculosis, localized and generalized infections, and disproportion between the fetus and the pelvis.

ARTHUR F. CIPOLLA, M.D.

Shock in Obstetrics. H. L. SHERRAN. *Lancet* Lond. 1948, 1.

Shock in obstetrics seems to be clinically and pathologically the same as shock in other types of cases except for the etiology.

This article is based on a clinical study and post mortem examination of 147 fatal cases of shock in relation to labor at the Glasgow Royal Maternity Hospital and on the clinical study of many other shocked women who recovered. The deaths occurred within 2 to 18 hours of the onset of shock. Many patients who died of shock also had hemorrhage, sometimes serious, but patients who died essentially as a result of hemorrhage are not included. The 147 cases were about one-third of those autopsied over a 10 year period.

The author believes that work done on shock in anesthetized animals is not comparable to their series of cases. The great majority of antepartals here reported were done within one hour of death and many within 15 to 30 minutes after death.

Clinical evidence suggests a very great reduction in blood flow through the skin muscles, and abdominal viscera. A pale, cold skin, the capillaries of which filled very slowly after pressure was applied furnishes evidence of this. Small contracted deep veins difficult to enter through which fluids had to be forced under pressure, furnished evidence of the slowness of the deep circulation. Even the deeper visceral organs showed evidence of this slowed circulation such as anuria of the kidney in shock. The author believes the brain is the last to show evidence of shock because patients frequently remained conscious until just before death.

He suggested that most of the manifestations of shock are due to a vasoconstrictor mechanism which reduces blood flow to the skin muscles, and abdominal viscera, although it does not interfere with the blood flow through the brain. This slowing of the blood flow through most of the body leads to reduction of the blood returning to the right heart which interferes seriously with heart function and leads to low pulse pressure and low arterial pressure.

In hemorrhage the vasoconstriction is temporary until the blood volume is restored. In pure shock the author states the body appears to bring the defense mechanism in to very powerful and protracted action.

to deal with a hemorrhage which has not occurred. This leads to poor venous return and a particular type of cardiac failure. He questions the use of adrenalin or pituitary extract in these cases. He says the production of this shock is by some unascertained stimulus, possibly nervous or biochemical. He believes transfusions are of little or no help.

The author gives the causes of shock in obstetrics as prolonged labor, ruptured uterus, retained placenta, and accidental hemorrhage, with particular emphasis on labors prolonged beyond 3 days and the third stage which has lasted over 2 hours.

BYRON F. HASKETT, M.D.

PUERPERIUM AND ITS COMPLICATIONS

The Venous System in the Puerperium (Sistema venosa e stato puerperale) ANTONIALE ZAMBONDI
Riv Ital gine 1947 30 135

Varicosities and phlebitis are the most important pathological conditions of the venous system in the puerperium.

There are two hypotheses for the origin of such varicosities during pregnancy: (1) compression of the blood vessels in the pelvis and (2) vasoconstriction produced by the pregnant uterus through other than mechanical factors. The first theory invites criticism because no varicosities are produced by tumors larger than the pregnant uterus at term, also twin pregnancy, hydramnios and genital tumors combined with pregnancy are observed without the presence of pronounced varicosities.

New biologic factors point to the importance of toxic and endocrine factors in the genesis of varicosities. Varicosities may develop simultaneously with the appearance of the first menstruation and show a certain periodicity.

Secretions of the pituitary gland seem to play an important role in the etiology of varicosities during pregnancy. The hormone regulates the tone of the smooth muscle. During pregnancy the muscles are relaxed and this may contribute to the development of varicosities.

Another theory states that some ovarian substance enters the circulation and directly influences the vasomotor apparatus.

Some authors call attention to the fact that chromaffin tissues of the suprarenal gland are depressed during pregnancy.

Three types of phlebitis may be distinguished—periphlebitis, mesophlebitis and endophlebitis—according to the location of the inflammatory process. From the bacteriological point of view two types may be distinguished—septic and aseptic.

The type that occurs during the puerperium is attributed to atony of the uterine wall with slowing up of the circulation and qualitative modification of the blood, such as an increase in fibrin content and an increase in the number of leucocytes. Septic phlebitis may be of embolic origin, the most frequent micro-organism found being the streptococcus.

ARTHUR F. CIPOLLA, M.D.

NEWBORN

A Creeping Infection of the Umbilicus (Die schleichende Nabelinfektion) B. DE RUDDER. *Dent med Wschr.*, 1947 73 497

The author reports 122 cases of umbilical infection in both bottle and breast fed newborn infants. Although this type of infection has been known for a long time it has occurred with increasing frequency since the war years. Of the total 122 cases 115 occurred since 1940 and 75 since 1945.

The infection is most often discovered in the period from the second to the sixth week of life. Externally there may be no sign of inflammation or granulation. Diagnosis is made by careful probing of the umbilicus which causes a discharge of pus, usually very minute in quantity. Pyogenic cocci are found on smear and culture.

In addition to fatal termination due to peritonitis (6 cases) and to umbilical sepsis (15 cases) a picture of severe nutritional disturbance, either acute or subacute, is seen. The majority of cases observed presented this disturbance.

Treatment consists of the administration of sulfonamides (or penicillin, the latter only recently) short wave diathermy and blood transfusion.

Of the 122 cases reported, 81 (66%) ended fatally in spite of intensive therapy.

WARREN R. LANG, M.D.

MISCELLANEOUS

The Principal Factors of Blood Sedimentation in the Course of Pregnancy and in the Sequel of Normal and Pathologic Labor (Les principaux facteurs de la sédimentation sanguine au cours de la grossesse et dans les suites de couches normales et pathologiques) J. BABIN and G. COMAS. *Rev Méd.*, 1947 2 396.

The authors have used the technique of Jayle and Badin in the study of pregnancy and the puerperium to establish the part played by the principal factors in the acceleration of the sedimentation speed which is always marked in these conditions. To avoid partial coagulation of the blood they have utilized a 20 per cent solution of sodium citrate at the rate of 1 c.c. in 10 c.c. of blood and have compensated for it by increasing the calcium concentration of the coagulating fluid (1.25 gm. of fused calcium chloride in 100 c.c. of physiologic saline solution).

In the course of pregnancy the sedimentation speed is accelerated from the second to third months on and increases up to term when it reaches its maximum. In order of importance the factors responsible for this acceleration are a considerable increase of the plasma factor in relation to elevation of the rate of fibrinolysis and a qualitative modification of this fibrillar substance, a progressive and very moderate increase of the serum factor and a decrease in the number of the red cells.

Normally, 10 days after delivery the sedimentation speed is close to that of the fourth to sixth

months of pregnancy but is nearly exclusively determined by the increase of the plasma and serum factors

In case of phlebitis or endometritis the sedimentation speed is very rapid and the factors responsible for the acceleration are, in the order of their importance, a strong increase of the serum factor, an increase of the plasma factor and a decrease in the number of the red cells. It is possible to use the finding of such a humoral syndrome in practice as it denotes in all probability a complication of the puerperal state even if the complication is not clinically apparent. Thus if the serum factor and the haptoglobin show values of less than 35 and less than 2 respectively the immediate danger of phlebitis may be rejected. If the serum factor is over 50 and the haptoglobin over 3 there is certainly an infectious condition present and the probability of phlebitis if the clinical signs are suggestive without yet being certain. In addition the measurement of the serum factor and of the haptoglobin seems to be an excellent means of verifying the evolution of phlebitis toward cure and of foreseeing possible recurrences. If the phlebitis heals without complications, the serum factor and the haptoglobin decrease but do not necessarily remain parallel: often one decreases before the other which suggests orientation toward cure. In any case, cure of the phlebitic process is certain only when the serum factor has become lower than 30 and the haptoglobin has become lower than 1.7

A syndrome similar to the former but less accentuated, is observed in the normal cesarean section.

In the sequel of normal pregnancy after a serious hemorrhage of labor the sedimentation speed is very rapid but the responsible factors are different, the most important being the decrease of the number of red cells: the other factors are in the order of their importance the increase of the plasma factor and the increase of the serum factor

RICHARD KROEL, M.D.

The Evolution of Pulmonary Tuberculosis after Delivery (*Evolucion de la tuberculosis pulmonar despues del parto*) VICTOR MANUEL AVILA B. FERNANDO RODRIGUEZ, and JOSE ORTIZ. *Obst. ginec. Bol. Mex.* 1947 5: 273.

In a study of 32,053 childbirths the authors found 658 women afflicted with pulmonary tuberculosis between the third month and second year following delivery.

In this 10 year period, the condition became worse in 28 per cent, remained stationary in 30 per cent, and showed improvement in 42 per cent. The disease grew worse in women of the ages between 25 and 35 years which was associated with an appreciable multiparity.

The mortality rate in this group was only 2.7 per cent.

Special importance is placed on the rest cure, but in some cases surgical treatment is necessary.

ANTHONY F. CIPOLLA, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Hypertension in Unilateral Renal Disease. HILBERT S. SABIN. *J. Urol.*, Balt. 1948 59 8.

The author reviewed the clinical observations and experimental work associating the various lesions of the urinary tract with elevated blood pressure. He states that from the evidence now available we can only conclude that in experimental renal hypertension interference with the renal circulation results in the release of a pressor substance, but we do not know how this is brought about. That certain hypertension with unilateral renal disease have been improved, and in some cases cured, by nephrectomy has been definitely shown. The author reports a case which seems to fall in the category in which nephrectomy is indicated.

The patient, an 8 year old white girl was in normal health until 3 years prior to hospital admission. At that time she first complained of severe headache accompanied by nausea and vomiting which persisted for about 8 hours and then disappeared. Similar attacks occurred at increasingly frequent intervals during the ensuing 3 years until June 1946 when she was experiencing them as often as 4 times weekly. On June 12 1946 she was hospitalized and an appendectomy was done. Twenty four hours following the operation convulsions developed and persisted intermittently for 23 hours. Between seizures, she complained of violent headache and vomited frequently. Following the second convulsion there was complete loss of vision.

The past history revealed no symptoms referable to the urinary tract.

Physical examination revealed a girl of 8 years who was complaining bitterly of headaches and was completely blind. Examination of the fundi showed two dipters of papilledema bilaterally. There were flame shaped hemorrhages in the macular regions. The retinal veins were distended and there was tortuosity of the arteries with some fragmentation. There was a soft blowing apical systolic murmur and accentuation of the second aortic sound. The blood pressure readings were as follows: right arm, 190/165 left arm, 185/160 right leg 220/170 and left leg 215/170.

The red blood count was 5,040,000 with 13.5 gm. of hemoglobin and the leucocyte count 7,700 with a normal differential. The urinalysis was normal except for the finding of 200 mgm. per cent of albumin and a few white blood cells in the urinary sediment. Urine culture was positive for the *Pseudomonas aeruginosa*. The Fishberg concentration test revealed specimens of 1:017 1:018 and 1:020 specific gravity. The blood nonprotein nitrogen was 24 mgm. per cent and 90 per cent of phenolsulfonphthalein was excreted in 3 hours. An intravenous pyelogram revealed prompt concentration of the dye by the left

kidney, which appeared to be considerably enlarged but otherwise normal. There was poor concentration of the dye by the right kidney which seemed to be markedly atrophic. Cystoscopic examination revealed a normal bladder. It was impossible to obtain a specimen from the right kidney. Indigo carmine was excreted in good concentration by the left kidney in 4 minutes. Retrograde pyelograms confirmed the previous finding of a large but otherwise essentially normal left kidney and an atrophic right kidney.

The patient was maintained on bed rest for a period of 6 weeks during which time her blood pressure fluctuated between 230/170 and 150/120 the average being 170/130. There was partial recovery of vision during this time but she continued to complain of almost constant severe headaches and the child suffered occasional bouts of nausea and vomiting.

On July 26 1946 the small atrophic right kidney was removed under ether anesthesia.

The specimen consisted of a right kidney and pelvis which weighed 16.5 gm. and measured 5 by 2.5 cm. The capsule was slightly thickened but stripped readily. The entire surface was markedly congested and there were a few small subcapsular hemorrhages. The pelvis seemed dilated and its walls were very thick and fibrous. On section there was a definite diminution of the amount of cortex and the division between the cortex and medulla was poorly defined. The blood supply was apparently normal. The majority of the renal parenchyma was replaced by fibrous tissue.

Microscopic examination showed remarkable fibrosis with sclerosis of the blood vessels and glomeruli many being completely obliterated and the walls of others greatly thickened. There was great distortion of the tubular structure and many tubules contained hyaline casts. There was diffuse leucocytic infiltration in some areas plasma cells predominating. The picture was that of chronic arteriosclerosis.

The diagnosis was chronic arteriosclerosis and chronic pyelonephritis.

Postoperatively the blood pressure fell to an average level of 130/90 with a range of from 118/80 to 136/94. There was prompt disappearance of the headaches nausea and vomiting. Following a course of sulfonamide therapy repeated urinalyses were normal except for a faint trace of albumin. Examination of the fundi revealed disappearance of the papilledema and retinal hemorrhages although blurring of the disc margins persisted. Vision was 20/30 in each eye. This improvement has now persisted for a period of 6 months, and while the blood pressure is somewhat higher than normal for a child of this age, still she has resumed ordinary activity and is clinically well.

results but small cysts in the remaining kidney may enlarge and the prognosis then becomes uncertain.

The disease in adults occurs with impairment of the general health between the ages of 40 and 60 years. In the final deterioration the fatal issue comes rather unexpectedly.

Only a small proportion of patients have hypertension. An advanced hypochromic anemia can exist as in any patient with marked renal impairment. The anemia is proportional to the increase in the non protein nitrogen and is held to be the result of toxic damage to the bone marrow caused by the uremia.

Acute symptoms arise in polycystic kidney disease in the form of fever and severe pain. It is only when the fever becomes prolonged lasting leucocytosis appears and massive hemorrhage or abscess formation takes place that surgical intervention becomes necessary.

Palpation of the kidney is considered to be the decisive factor in establishing the diagnosis. In early cases the diagnosis can be established only after x-ray examination.

The exposure of the kidney with puncture of as many cysts as possible the Rovsing operation was first regarded as an emergency operation a purely palliative intervention. The operation of puncturing cysts now has become more common in cases in which there is rapid destruction of kidney tissue.

Attacks of pain and fever may regress under treatment with analgesics and antispasmodics. Rovsing's operation should be performed for

1. Perinephritis and infected cysts.
2. Large hemorrhages.
3. Threatened uremia.
4. Rapid deterioration of kidney function.
5. Rapidly increasing hypertension.

In the first case the author reported the patient had an enlarged left polycystic kidney. Many of the cysts were punctured some of them were opened and the outer walls were excised and painted with a proprietary sclerosing solution. The right kidney was apparently normal. The patient had a favorable result. The second and third cases were only temporarily improved by this type of operation.

The author concluded that the results of the Rovsing type of operation must be judged on the basis of urological examination renal function tests urinalysis intravenous urography and determination of the blood pressure. The patient's subjective symptoms are of only secondary importance in evaluation of the results of operative removal of the renal cysts.

CORRAD A. KUTERN, M.D.

Ureterointestinal Anastomosis. R. H. FLOCKE, J. Urol. Balt., 1948, 59, 21.

A review of the literature in regard to uretero-intestinal anastomosis reveals that all of the many different types of operations may be divided into the two following classes:

1. Modification of Coffey's technique in which the ureter is divided and imbedded submucosally in its intestinal bed.

2. The method using the intact ureter in which the ureter is not first divided but is implanted submucosally in its intestinal bed and later communication with the bowel and division of the distal ureter is carried out.

Difficulty in connection with the first type of operations have been early obstruction and infection of the urinary tract, leakage with peritonitis or extraperitoneal leakage if an extraperitoneal modification of this technique was used and later obstruction and urinary tract infection. It has been shown that inflammation in the periureteral bed is the cause of these difficulties and that the breakdown is due essentially to a spread of infection from the lumen of the bowel upward to the periureteral bed. There has been a lesser incidence of these complications in young patients in good general health and in more recent cases in which newer chemotherapeutic agents were available. However the uncertainty of the occurrence of these complications in all groups is outstanding.

The difficulties which arise in connection with the second type of operations are of a different sort. Inasmuch as the ureters were implanted intact, early breakdown of the anastomosis with leakage and peritonitis did not occur. However, urinary tract obstruction and infection occurred as did anuria or marked oliguria when bilateral anastomosis was performed. If these were overcome or did not occur then difficulties arose with regard to making the intestinal communication. This was accomplished by various methods the results of which were sometimes uncertain or required a rather extensive secondary procedure. Good results have been reported in both groups however the results are uncertain. This uncertainty is apparently related to local breakdown in the anastomosis in operations of the first type, and to surgical edema kinking or technical difficulty in making the communication in operations of the second type.

The author's experience coincided with the reports in the literature and the review of that material showed that in the cases in which the intact ureter was used early breakdown never occurred, while in the cases in which the intact ureter was not used there was a definite incidence of local infection and breakdown which occurred even with careful bowel asepsis careful placing of sutures, and avoidance of contamination. This occurrence was uncertain, but more frequent in older individuals than in children. It occurred even with the use of very intensive chemotherapy. Injection studies revealed that the ureter has an excellent arterial supply which is distributed from both the proximal and distal ends and along its course. The arterial supply within the ureteral wall could be outlined by injection from either end. However it was found that if one injects the arteries of the human cadaver having first divided one ureter as in operations of the first type, the density of the arterial supply in the divided ureter seemed definitely less than in the undivided one. This would seem to indicate that its nutrition

Fig. (R. H. Flocks). A method of ureterointestinal anastomosis. a, Exposure. b, Incision is made in parietal peritoneum, and the ureter is exposed and brought up into the abdominal cavity. c, Incision is made along the surface of the sigmoid for about $\frac{1}{2}$ inch, down to the mucosa. The rectal tube, which has been pushed up into the lumen of the sigmoid, can be seen underneath the mucosa. The incision is in the wall of the bowel and the exposed portion of the ureter are fitted together so that they will fit nicely. d, A small incision has been made into the ureter and No. 7 or

No. 8 ureteral catheter is passed up into kidney pelvis. A tiny incision is then made in the mucosa of the bowel right over the rectal tube. I to this the other end of the ureteral catheter has been placed. It is pushed down into the lumen of the rectal tube so that it comes out of the anus underneath the drape. An assistant then pulls out the catheter so that the sides of the opening of the ureter and the opening of the bowel can be approximated with interrupted black silk sutures about the ureteral catheter in exactly the correct position.

had been definitely disturbed and thus its viability and ability to resist infection had been impaired. Certain clinical observations seem to confirm this concept. It has been observed that the end result of cutaneous ureterostomy varies in an uncertain manner. In some cases the operation left a good, healthy stump and in others the stump sloughed down below the skin. Similar uncertainties have been observed in tube grafts, since they depend on the arterial supply from both ends of the tube for nourishment. These observations would seem to indicate that the principal advantage to be derived by the use of the intact ureter is the improved blood supply and consequently improved tissue viability, which in turn aids in overcoming any infection which might occur in connection with the anastomosis.

above and below. In the severed ureter blood may enter only from the proximal portion. Slight edema causing pressure may so deplete the blood supply that even though slough due to this alone does not occur resistance to infecting organisms is greatly reduced. Therefore the author believes that the importance of the principle of the intact ureter is not invariably a question of contamination of the ureteral bed with organisms, but rather the maintenance of adequate ureteral blood supply.

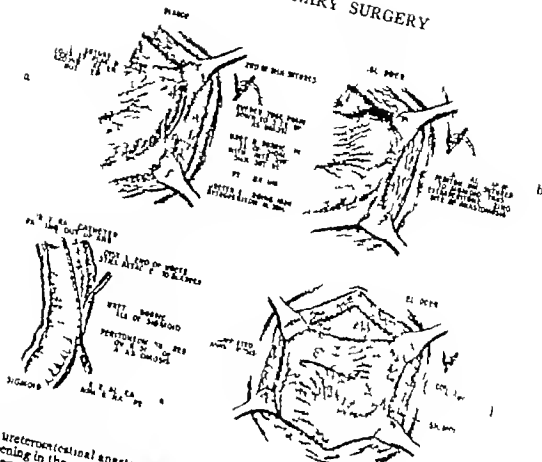

Fig. 3. A method of ureteroenteric anastomosis (continued). *a*, After the opening in the ureter and the opening in the bowel have been approximated snugly about the ureteral catheter the whole region is buried with interrupted black silk sutures by suture of the edges of the incision in the bowel over the ureter it being buried for a distance of about $\frac{1}{4}$ inches. *b*, The whole region of anastomosis is then buried with interrupted black silk sutures, with suture of the parietal peritoneum to the wall of the bowel over the region of the anastomosis and complete suture about the region of the anastomosis. The silk suture which has been placed about the distal portion of the ureter is brought out through a stab wound just in front of the anterosuperior iliac spine and the region of the anastomosis is

also drained with a rubber tube drain and sometimes a pack. This silk suture is tied two weeks later. (The second stage consists of tying off the ureters a weeks later after this procedure. They are tied off by simply tying silk sutures extraperitoneally through stab wounds on each side. This is surprisingly easy to do and takes only about 10 minutes. Thus the operation has been performed relatively easily.) *c*, Diagram showing cross section of the region of anastomosis. It illustrates the ureteral catheter as it goes from the ureter through the incision in the ureter and bowel out through the lumen of the bowel and out through the anus. *d*, Completed operation on both sides.

edema or kinking is obviated and (3) because the anastomosis is completed in the first stage, no second operation of great magnitude is necessary inasmuch as the second procedure is done extraperitoneally away from the region of the anastomosis and is a minor one.

The patient is prepared by the use of the Levine tube, parenteral feedings, and sulfasuxidine given by mouth for several days prior to operation. Enemas (until clear) are given the night before the operation and the rectosigmoid is irrigated thoroughly again after the patient is on the table. A silk and wax rectal tube is then inserted and left in place. A suprapubic incision is made and the abdominal cavity entered. The region of the sigmoid and the lower portion of the ureters are exposed. The peritoneum is incised, and the intact ureters are freed by blunt dissection. A closely adjacent portion of the

sigmoid is selected and a bed for the ureter prepared by splitting the serosa of the sigmoid. Three traction sutures of fine black silk are then placed in the lateral free flap of the bed and passed under the ureter to facilitate its approximation to the open bed. The rectal tube is now manipulated so that its open end is presented to the previously prepared bed of the sigmoid beneath the mucosa, and a single black silk suture is passed through the serosa of the ureter and the muscularis of the sigmoid on either side of the open end of the rectal tube. The ends of the suture are held in position but not tied. A small stab wound is now made in the sigmoid mucosa penetrating into the open end of the rectal tube. An opening of adequate size is made in the rectal tube. An opening corresponding level between the ureter at the corner. A ureteral catheter is then inserted in the ureteral opening up to the kidney pelvis and the

opposite free end inserted through the opening in the sigmoid into the rectal tube. The rectal tube is now withdrawn gradually until the ureteral catheter can be grasped and straightened out by the assistant. The previously fixed silk sutures about the region of the anastomosis are now tied and the bed in the sigmoid is closed over the ureter by means of later ruptured black silk sutures. The region of the anastomosis is extraperitonealized by suturing the lateral leaf of the parietal peritoneum to the sigmoid. A heavy steel or silk suture is placed untied around the distal portion of the ureter emerging from the anastomosis and is brought out through a stab wound near the anterior superior iliac spine, extra-peritoneally and adjacent to a pack or rubber tube which maintains an open anus to the site of the ligature. After a similar procedure is carried out on the opposite side, the midline incision is closed in the usual manner without drainage. The ureteral catheters are now secured to the skin adjacent to the anus by steel sutures. It is usually not difficult to keep the catheters draining freely but if they clog the urine appears promptly in the rectal tube which is left in place after the operation. A Wangenstein suction apparatus is used for 3 days, following which the diet is gradually increased. Two weeks later under pentothal anesthesia the sutures in the distal ureters are tied under vision by enlarging each lateral incision slightly and the drains in the small lateral incisions are removed. By this time the patient is operating a normal diet, and is beginning to establish his new bowel habits.

Thus a new method of ureterointestinal anastomosis prior to total cystectomy is presented which is simple and has the following advantages: (1) by the use of the intact ureter the blood supply to the region of the anastomosis is maintained; (2) by the immediate creation of an anastomosis under vision around the ureteral catheter the danger of ureteral obstruction due to surgical edema or kinking is avoided; (3) since the anastomosis is completed in the first stage no second operation of great magnitude is necessary; and (4) ureterointestinal communication can be accomplished under direct vision.

In 12 patients a total of 23 ureters were transplanted into the colon by the method described. All of the patients but 2 were between 54 and 74 years of age. These 2 were 37 and 45 years of age respectively. In no case has there been local breakdown or death due to the operative procedure. In 1 case death occurred while the patient was still in the hospital, 4 weeks after operation. The cause was cardiac failure. The transplantation had been working nicely but postmortem examination showed a large inoperable carcinoma of the bladder. The left kidney was destroyed and the ureter therefrom had therefore not been transplanted. The ureterointestinal anastomosis had healed perfectly 4 weeks after operation.

The postoperative course of the 11 other patients was not remarkable. Studies of the renal function were normal and the postoperative intravenous

pyelograms were either normal or showed moderate hydronephrosis. The oldest patient was examined 9 months following the transplantation and showed a normal pair of kidneys.

BLADDER, URETHRA AND PENIS

Multiple Calculi of the Urinary Bladder (Litiasis vesical multiple) P. GAURA RASPALE. *Arch. ital. med.* 1947 4 35.

Twenty five per cent of the author's 40 patients had more than one stone in the urinary bladder the number ranging from 1 to 44. Although urinary stones are usually observed in elderly persons, one patient was 6 and another 16 years of age. With the exception of one patient, all of them belonged to the male sex.

In 8 of 10 patients lithiasis was associated with a fibroadenoma of the prostatic gland in one with cervical scleroses and in the last with stenosis of the urethra and diverticulum of the bladder.

Primary stones or those originating in the bladder consist of urates and oxalates, while secondary stones or those descending from the kidneys are formed by phosphates.

GENITAL ORGANS

Contribution to the Study of Free Bodies in the Vaginal Sac of the Testicle (Contributo allo studio del corp liber della vaginale del testicolo) GIOVANNI D'ERICO. *Gior. ital. chir.* 1947 2 435.

At operation for right hydrocele of 2 years' duration in a man of 53 the author found a white hard fibrous spherical body, the size of a small grape, floating in the fluid the testicle was smaller and softer than normal. The head of the epididymis was enlarged and had a swelling on its upper external aspect which on incision allowed escape of a little limpid fluid and a second spherical body identical to the first. The head of the epididymis presented numerous small cysts involving predominantly the back of the upper pole of the epididymis one of the cysts was nearly pedunculated as it was free from the epididymal surface for about three-fourths of its circumference. Orchiepididymectomy was performed and recovery followed.

There is no doubt that the nucleus of these free bodies was formed from small epididymal cysts. This is proved by (1) the histologic finding of lacunar spaces grouped in the center of the free bodies and filled with amorphous substance similar to that found in the pedunculated subepididymal cyst; (2) the presence of this pedunculated cyst which in time would probably have given rise to the formation of another free body; and (3) the absolute integrity of the vaginal sac of the testicle. The presence of the epididymal cysts may have been due to a gonorrhea incurred by the patient at the age of 18.

The similarly spherical form of the two free bodies, despite the difference in their environmental

conditions demonstrates that eventual mechanical causes depending on the milieu in which the free bodies have developed cannot have any importance in determining their shape. This stands in contradiction to the opinion of some authors who have claimed that the spherical form is the result of the capacity of the bodies to revolve freely in the ambient cavity.

The structure of the free bodies consisting exclusively of fibrillary tissue arranged in concentric layers with complete absence of any cellular elements could constitute a proof in favor of the extracellular origin of the fibrilla, whether they are considered as a differentiation of a primarily amorphous fundamen- tal substance or as a process of fibrous evolution of the proteins contained in the ambient fluid. It might be that the cells generating the fibrilla have been destroyed secondarily or completely trans- formed into fibrils as the nutritional condition of the free body deteriorated but in such a case it would be necessary to admit that at the time of operation the free body had already exhausted its capacity of further increasing in volume.

MISCELLANEOUS

Nonparasitic Lymphuria; Clinical and Therapeutic Study of a Case (Linfuria non parasitaria, considerazioni cliniche e terapeutiche a proposito di un caso) E. MALAN and G. AREZZI. *Boll. Mem. Soc. Pneumot. chir.*, 1947 17 513.

A 13 year old girl sustained a severe contusion of her right knee at the age of 8 years and since that time had pain, swelling, and contracture of the involved articulation. In course of time the condition became complicated by febrile episodes, dysuria, increased frequency of urination, and emission of turbid urine containing gelatinous pinkish material. The urine had a specific gravity of 1.022, acid reaction and on standing formed 3 layers, the lowest layer contained epithelial and pus cells and fat globules, the central layer had a milky appearance and the uppermost layer was formed of a white gelulum. Each episode of ischuria was concurrent with severe pain in the right knee. Repeated search for filaria in the blood and urine gave negative results. While intravenous urography failed to reveal any pathology, ascending pyelography visualized on the right side the perirenal

lymphatic network, the penureteral lymphatic plexus and the lumbar lymphatic duct.

The right kidney was exposed and stripped of perirenal tissue to isolate connections with the lymphatic system. Following the operation an extensive edema developed in the right gluteal and lumbar regions and in the right lower extremity. After a series of intravenous injections of gonacrine the condition was found to be improved and the urine cleared.

There was no evidence of a congenital neoplastic syphilitic or tuberculous origin of lymphuria. Probably subacute lymphangitis following the trauma of the knee produced stasis and caused the formation of fistulas between the lymph vessels and the right kidney.

Control of Urinary Tuberculosis. GEORGE E. SLOTKIN. *J. Urol.*, Balt. 1947 58 464.

A preliminary report is made of the use of streptomycin in combination with chaulmoogra oil in the treatment of inoperable or bilateral renal tuberculosis. The report includes 6 active cases of inoperable and bilateral renal tuberculosis treated since January 1, 1947 and also in vitro studies and studies of guinea pig inoculations.

The author made use of the *Mycobacterium phlei* for the studies in vitro. Broth suspensions of this organism were inoculated into various dilutions of chaulmoogra oil and streptomycin. It was clear that exposure to chaulmoogra oil caused considerable inhibition of growth and that the *Mycobacterium phlei* is made more sensitive to streptomycin by exposure to chaulmoogra oil for a period of 24 hours. Inoculation of 7 guinea pigs with tuberculosis was done. 3 received no treatment and upon autopsy showed marked involvement with the disease. One pig treated with streptomycin alone, and a treated pig with streptomycin and chaulmoogra oil showed no evidence of tuberculosis.

A total of 6 patients with bilateral inoperable renal tuberculosis received treatment with chaulmoogra oil and streptomycin for 30 days. All of these patients had proved bilateral renal tuberculosis, in most cases with involvement of the lower urinary tract. In every case the disease was arrested by treatment, and guinea pig inoculations following therapy revealed no evidence of tuberculosis. In view of these striking results further investigation is planned by the author.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Osteofibroma or Circumscribed Fibrous Cystic Osteodystrophy (Osteofibroma or osteodystrophia fibrosa circumscripta)? ERZO DE MARCONI. *Chir. urol. med.* 1947 51: 51

The roentgenologic diagnosis of circumscribed cystic fibrous osteitis, solitary bone cysts, and giant cell tumors offers great difficulties. The term "fibrous osteitis" includes Recklinghausen's generalized fibrocystic osteitis, circumscribed fibrous cystic osteitis, and Paget's disease. Difficulties may be encountered in the differential diagnosis between fibrous osteitis and giant cell tumors.

A 20 year old woman was admitted to the hospital with complaint of pain in the left hip. Five months prior to admission she sustained a slight injury to her left hip and 2 months later the pain occurred.

Roentgenograms revealed a single cyst of the size of a hen's egg in the left femoral neck. The lower border of the cyst apparently broke through the cortex of the femoral neck.

Absence of periosteal reaction and of sequestra and also the normal temperature excluded pyogenic osteomyelitis. Tuberculosis, syphilis, and echinococcus disease also could be excluded. The integrity of all other bones favored elimination of Recklinghausen's disease, Paget's osteitis, and Brodie's abscess. A bone cyst, giant cell tumor and circumscribed fibrocystic osteitis were considered. Biopsy established the diagnosis of a fibroma.

During the entire year following the operation no reparative processes could be detected and therefore a bone graft from the tibia was inserted. Two years later the patient's gait was normal, she had no pain and x ray studies showed restitution of the bone. The histologic examination of a specimen taken at the second operation suggested the diagnosis of an osteofibroma, a relatively rare condition.

Ollier's Disease and Its Relation to Other Forms of Chondrodysplasia. A. LANGENSKIÖLD. *Acta orthop. scand.*, 1947 17: 95.

About 50 years ago Ollier called attention to a growth disturbance associated with unilateral thickening of the ends of long tubular bones which he called dyschondroplasia. The author adds 3 cases which correspond with the condition originally described by Ollier but are classified as chondrodysplasia. The first case was that of a 6 year old boy whose right leg showed a shortening of 6 cm. The roentgenograms showed areas of irregular densities in the ilium, thickening of the femur and coxa vara. The upper extremities and the tarsal bones showed similar abnormalities. The second case was that of a 56 year old woman who was first examined at the age

of 4 and followed up until the present date. This patient showed multiple lesions in the pelvis and in the long tubular bones. The right leg was about 12 cm. shorter than the left. There was an exostosis on the distal portion of the right femur and there were hemangiomas of the skin.

This condition appearing in the literature under different and various names, was accepted as one with a benign course. One investigator however claimed that the cartilaginous foci in Ollier's disease did not necessarily stop growing when the individual ceased to grow but continued to increase in size. They were therefore "potentially malignant lesions."

By means of schematic drawings and by roentgenograms it is demonstrated how these cartilaginous lesions appear in the metaphyseal regions. Portions of the epiphyseal plate are separated but continue to proliferate and move away proximally to this plate. This may occur near the cortex or more toward the middle portion of the epiphyseal plate. Ranvier pointed out that the osteogenic layer of the perosteum probably originates in the undifferentiated cells primarily lying within the epiphyseal cartilage.

The differential diagnosis between Ollier's disease and enchondromatosis is based on the fact that in the latter the cartilaginous foci are round or oval and are potentially malignant, while in the former the cartilaginous foci are elongated because of the appositional type of growth inherent in cartilage originating from the epiphyseal plate. Although most observers are inclined to separate tumor distinctly from all other growth processes, the fact cannot be disregarded that there are stages of transition between hyperplasia and autonomous tumors.

Most workers consider Ollier's disease, enchondromatosis and multiple cartilaginous exostoses under the common heading of chondrodysplasia since features of all three conditions may be found in the same individual.

GROENK L. RANIER, M.D.

Osteochondromatoma of the Sternum: Use of Tantalum Plate as a Prosthesis. R. AARVOLD. *Arch. Surg.* 1947 55: 681

A 41 year old farmer was admitted to the hospital because of a tumor of the sternum which grew in 18 months from 5 cm. in diameter to a mass which measured 10 by 11 by 13.5 cm. The tumor the underlying sternum and portions of the ribs were removed *in toto*. A tantalum plate 0.032 cm. in thickness was used to cover the defect.

By using this plate paradoxical respiration was prevented in the immediate postoperative period. On the seventh postoperative day a considerable amount of fluid was observed in both pleural cavities. On the tenth day serosanguinous fluid escaped from the distal portion of the incision. On the fifteenth day edema and tenderness of the left calf developed. This condition improved after ligation

of the left femoral vein. Serosanguinous drainage continued and the tantalum plate was removed on the sixty-third postoperative day. The soft tissue had sufficiently thickened to prevent paradoxical respiration. The wound healed satisfactorily. The tantalum plate served well as a temporary prosthesis.

GEORGE L. REES, M.D.

Retroposition of the Vertebrae as an Early Sign of Tuberculous Spondylitis of the Lumbar Spine.
LAUS HAAKSTAM. *Acta orthop scand* 1947 17 31

Instability between the vertebrae of the lumbar spine may arise at an early clinical state—with tuberculous spondylitis as well as with disc degeneration. In the roentgenogram a retroposition might occur before any tuberculous changes in the vertebrae themselves are visible. Such a picture favors the belief that the process is to be found in either vertebra adjacent to the injured disc.

A normal disc fastens the adjacent vertebrae very rigidly to each other and parallel displacements between the vertebrae do not arise in such cases. In stability occurs when the discs are degenerated and retroposition arises before the injured disc is entirely destroyed. After the disc substance is entirely destroyed and has perhaps been replaced by unspicific connective tissue and the surfaces of the vertebrae almost seem to touch each other very little if any retroposition is visible any longer.

In one of the authors' cases the roentgenogram showed osteoporosis and retroposition but no destruction of any vertebrae or discs. The author described 4 cases which showed that retroposition occurred in connection with tuberculous destruction of the vertebrae and the discs of the lumbar spine before the body of the vertebra had collapsed.

Tuberculous spondylitis may develop just as any other kind of tuberculosis of the bones does without any changes that can be visualized in the roentgenograms. Rather large tuberculous vertebral foci have been found at autopsy although the roentgenograms were negative.

In 1943 Severin found retroposition in about half the number of 266 patients showing signs of degeneration of the intervertebral discs. This retroposition occurs in the cranial as well as in the caudal part of the lumbar spine. Diagrammatic sketches were made showing the degree of retroposition in several of the cases.

C. FRANK GÖRANSSON, M.D.

Giant Cell Tumor of the Lumbar Spine (Tumore a micropilares del rachide lombare) G. CORRAZCHI. *Rev. medica* 1947 31 139.

Giant cell tumors are most frequently found in the metaphyses and epiphyses of long bones and in the upper jaw but rarely in the spine.

The author observed a giant cell tumor in a 35 year old patient. The tumor located in the third lumbar vertebra, began causing pain along the lower end of the spine 7 years prior to admission to the hospital. Roentgenograms showed a deformity of the involved vertebra with slightly narrowed but

preserved intervertebral spaces. A large shadow was contiguous with the right margin of the affected bone. The tumor was removed and the patient made an uneventful recovery.

The diagnosis is usually based on x ray findings which show characteristic changes in the structure of the involved bone. Contrary to the giant cell tumor Pott's disease shows arthrotropic tendencies. Sarcoma usually does not invade the discs, but it affects the bodies of one or more vertebrae and produces a more or less circumscribed shadow with irregular outlines. Chondroma has a spotted appearance minute shadows intermingled with light areas.

A complete removal of the tumor should not be attempted in each instance because radical operation is connected with a very high mortality. A partial removal of the tumor followed by the application of a cast, as in the author's case, may be sufficient.

JOSEPH K. NARAY, M.D.

Derangements of the Knee. PAUL R. LIPKOWSKI and MELVIN HENRIKSSON. *J Am Med Ass.* 1947 135 837.

The cases in which arthroscopy of the knee has been performed at the Mayo Clinic for derangements of the meniscus through 1944 were reviewed in two series. The first series included records of patients who had suffered internal derangements of the knee to and including 1933. The second series included cases in which arthroscopy was performed in the years 1934 through 1944. Arthroscopy was carried out 664 times for 655 patients who had the condition in question.

The diagnosis of meniscal injuries or abnormalities can be established best by the careful taking of a history in which locking of the knee joint followed by pain and swelling is elicited. This triad was present in 70 per cent of the patients.

In many cases of injury to the meniscus there are associated injuries to the ligaments or of the articulating surface of the patella. In this group of patients the results of surgical treatment are likely to be considerably worse than among those patients whose injury is confined to the semilunar cartilages. In the more recent of the two series the results of excision of the torn portion of the cartilage and the results of excision of the entire cartilage were essentially the same.

SURGERY OF THE BONES JOINTS MUSCLES TENDONS, ETC

Fundamental Concepts and Treatment of Volkman's Completely Developed Contracture (Conceptos fundamentales en el tratamiento del Volkman completamente constituido) PEDRO V. FERNANDEZ. *Rev. Soc. Cir. Uruguay* 1947 18 202.

The complete evolution of Volkman's contracture may require several years and it is a grave error to undertake treatment of the condition before termination of the process.

The motility of the fingers is preserved when the wrist is kept in flexion but if the wrist is extended extension of the fingers becomes impossible because of the shortening of the flexor muscles. Disturbance of balance between the osseous and the musculo-tendinous systems of the involved extremity is responsible for the inability of the patient to extend his wrist. It follows that either the bones must be shortened or the muscles and tendons must be lengthened. The author favors the first procedure. Delayed union the formation of pseudarthrosis deviation of fragments, angulated callus, and radioulnar synostosis usually can be avoided with the proper technique.

The author favors atypical resection of the wrist and arthrodesis because the resulting impairment of the function of the wrist is minimal. The operation is indicated in cases with considerable flexion of the hand and marked shortening of the forearm.

If the shortening of the forearm and the flexion are moderate a partial resection of the radius and the ulna is indicated.

It should be remembered that lowering of the insertion of the epitrochlear group of muscles causes a diminution of their tone.

Elongation of tendons is a technically difficult procedure. It is necessary to suture 21 tendons. In exceptional cases tenotomy of the flexors proper of the wrist may be necessary to supplement other therapeutic procedures.

In many instances a combination of several procedures, such as ankylosis of the wrist and interphalangeal articulations, tenotomies of several muscles, resection of the elbow and reinsertion of the epitrochlear group of muscles may be necessary.

JOSEPH K. KARAT, M.D.

Reparative Surgery of Severed Tendons and Nerves of the Hand HANS BIAT, *Surg. Clin. N. America*, 1947 27 1474.

The author believes that primary repair of injured tendons and nerves may properly be done in clean wounds up to 6 hours after the injury. His technique consists of a thorough cleansing with soap and water and alcohol. The operation is done under general anesthesia, and a blood pressure cuff is placed on the extremity for a tourniquet. The operation includes an excision of the wound edges, and gentle handling of the nerves and tendons is stressed.

In exploring the wound one should first locate the nerves, then the arteries and veins, and finally the tendons. It is usually necessary to enlarge the wound to find the proximal tendon ends, and the distal ends can usually be brought into the wound by moving the fingers in the appropriate direction. One should respect the tendon ends back to healthy tissue before repair of the tendon by any of the commonly recommended tendon suture methods. In injuries of the palms the proximal end of the tendon is usually retracted so far that a small incision must be made above the wrist to locate it. The tendon is then pulled into the original wound by means of a tem-

porary silk suture threaded on a probe. If both the sublimis and the profundus tendons are injured within the sheath, only the profundus should be repaired, as it is not proper to have two sutured tendons within the same sheath where they would become adherent.

Secondary suture is indicated when primary suture has failed or in wounds in which the 6 hour time limit has passed or contamination or unhealthy tissue is present. The procedure is difficult because of the adhesions which have formed and the retraction of the tendon ends. It is often necessary to graft tendon material to cover defects. One should not do tendon repairs in the presence of stiff joints.

The difficulties of secondary suture are much more serious if a primary suture has been done and failed. This is one of the reasons why one should not attempt primary suture unless conditions are definitely favorable.

One should do a secondary suture through enlarged incisions so that adequate exposure is obtained. All scar tissue should be excised, and devitalized unhealthy tissue should be debrided. Sometimes fat grafts obtained in the thigh must be placed between structures when dense scar tissues make a gliding surface otherwise unobtainable.

The after treatment of these tendon sutures depends upon a proper understanding of the two stages of tendon healing. The first the proliferative stage lasts a week, during which connective tissue callus unites the tendon ends. No motion should be permitted during this period, as early motion favors adhesion formation. The best splint is made of a molded plaster. The author removes this splint in 4-6 weeks, removes the sutures, and begins gentle motion under water. The splint is discarded in 3 weeks, and active and passive exercises with massage and heat are begun. Occupational therapy is useful.

Appropriate diagrams and a few illustrative cases are presented. NEWTON C. MEAD, M.D.

Contribution to the Technique in Fusion Operations on the Spine. ARTHUR BRAD, *Acta orthop scand* 1947 7.

The results of fusion operations on the spine were judged clinically by the degree of fixation attained, and roentgenologically by the quantity of newly formed bone around the transplanted graft. The author summarizes the results of 48 operations for fusion of the spine by various methods for tuberculosis spondylitis, scoliosis, etc.

It was easier to judge the results in the lumbar spine than in the thoracic area. In the thoracic area it is difficult to observe the space between the spinous processes because of the position of the ribs. The author believes there is evidence both experimental and clinical, that every transplanted bone, whether large or small, thick or thin, will die. After transplantation there is no growth of osteoblasts from the haversian canals and the calcium in the necrotic grafts plays no role as regards the regeneration of the bone. The necrotic graft is gradually replaced by

living bone through substitution processes which take a longer time according to the size of the transplanted bones. Such necrotic massive grafts which have lost the cells and the structure of living bone, and which for the most part consist only of lime will give to the roentgenogram some suggestion of solidity and strength but represent, in the literal sense of the term, a white sepulchre. Therefore if the grafts disappear rapidly and if signs of the formation of new bone appear the prognosis is good.

The Albee method of spinal fusion was used at first, but this was abandoned subsequently because of the difficulty in getting the graft to hold on to the spinous process of the healthy vertebrae above and below. Six Albee transplantations were studied. Six months later not a single case was found to have signs of new formation of bone and clinical fixation was seen in only two of the cases. In subsequent months the remaining cases showed undoubted new formation of bone though one case was listed as doubtful. When the Albee operation was modified by using a thin instead of a thick graft from the tibia the result was apparently worse. The result was found to be a little better in cases in which two thin grafts were inserted into grooves chiselled in the base of the spinous process after removing the outer most parts of the spines. In this last series of cases and in a few of these there was new formation of bone. The author maintains that the use of thick transplants hinders the building up of living bone tissue between the arches. Orell's fixation operation in cases of tuberculous spondylitis was discussed.

A procedure was adopted which consisted primarily in providing a space over the arches where the new formation of bone may proceed unhindered. Secondly this space is filled with the elements from which the new bone tissue is to develop. A semi-flexible slice of bone covered with periosteum is removed from the tibia and is placed towards the muscles which are loosened from the spinous process and back into place over the grafts by means of small pieces of bone likewise taken from the tibia, which are stretched out between the spinous processes and the semiflexible piece of bone periosteum. The author further modified this procedure by filling the space between the slice of bone (which keeps the muscles out) and the spinous process with bone shavings from the tibia.

The entire operation is performed under local anesthesia. It is simple and it can be performed in cases of the most extreme deformity of the spine. The after treatment is of short duration due to rapid setting in of the process of substitution and to active regeneration of the bone. As strain on the spine at an early point of time does not disturb but rather promotes this process the patients can get up after 6 weeks. The duration of the subsequent treatment with a plaster corset will be comparatively short but varies for each individual and is dependent on the degree of regeneration found on x ray examination.

A total of 19 operations was performed by this method. Thirteen cases were analyzed in 11 of these new formation of solid bridges of bone over the arches was found 6 months after the operation. Follow up studies in 6 of the 19 patients were in sufficient for discussion.

C. FRED GOEDHOUT, M.D.

Joint Mobilizing Operations on the Hip, Knee, and Shoulder for Complications following Trauma
PAUL H. HARMON *Am J Surg*, 1947 74 598

Present degenerative joint disease follows most major or repeated minor trauma especially in weight bearing joints. In 35 cases of such hip joint arthritis the condition is thought to have been precipitated by trauma. Cup arthroplasty was done in these selected cases to increase the range of motion and decrease attendant pain. Advanced degeneration of articular cartilage contraindicates the arthroplasty as does antecedent infection in the hip joint.

Plastic cups used in the early cases tended to wear thin or crack. A new type of cup turned from a solid block of plastic to a uniform three-sixteenths of an inch has proved satisfactory. A minimum of reshaping of the femoral head other than removal of osteophytes and making the major reconstruction that of the acetabulum helps preserve the integrity of the reflected joint capsule and is advised by this author.

Excystectomy alone is done in cases in which inspection shows fairly good articular cartilage, and motion is improved by the removal of osteophytes from the acetabulum and femoral head.

Buck's extension with an internal rotator strap is the only apparatus used postoperatively. Adduction of the leg is avoided. Physical therapy is begun at 3½ weeks and nonweight bearing crutch walking from 4 to 8 months, depending upon the extent of the surgery.

In from 5 to 7 years after operation, 61 per cent of the whole group showed good results i.e. an increase in motion and freedom from pain.

The subject of degenerative changes in the knee summarized. A modification of the Magnusson technique for patelloplasty was carried out in 37 cases and after a period of from 8 to 3 years the results in 35 cases were classed as good. The patients had little or no pain and at least 130 degrees of active and passive motion.

Six cases of arthritis of the head of the humerus are reported. In 2 of these partial resection of the humeral head was carried out and in 4, osteophytes were removed from the posterior glenoid rim. Five of these patients showed an improved range of pain less motion.

FRANCIS E. BRENNER, M.D.

Epiphyseolysis Capitis Femoris Treated by Drill
Ing. SVEN KLOER. *Acta orthop scand*, 1947 17 81
Since 1939 one group of patients with slipped femoral capital epiphysis was treated by drilling of

the femoral head and another group afflicted with the same disease was treated by fixation of the slipped femoral capital epiphysis by means of a nail.

The first group consisted of 4 female and 11 male patients between the ages of 11 and 18 years who had early to moderate slipping. Drilling was employed to accomplish fusion between the femoral head and neck. Patients with marked slipping (exceeding one-third of the epiphyseal diameter) were treated by osteotomy and were not included in this series. Patients with acute slipping were also excluded. The symptoms of pain and limp had persisted for from 5 to 50 weeks prior to entry into the hospital.

All patients were initially treated with traction on the extremity for 4 weeks, one tenth of the weight of the patient being used as traction pull. Then three channels were drilled through the femoral neck into the capital epiphysis with a 3 mm. drill. Post-operatively the patients were confined to bed for from 4 to 8 weeks and were then allowed to ambulate with the help of crutches. No weight bearing of the affected extremity was permitted until fusion between the capital epiphysis and neck was visualized on the roentgenogram.

Bony fusion was obtained in all cases. An excellent result was observed in 11 cases—there were no subjective complaints, there was less than one third loss of motion in the hip joint and the patients were able to do the same work as prior to the onset of symptoms. There were good results in 8 cases and poor results in 3 patients.

Traction did not seem to change the position of the slipped epiphysis. Changes in the femoral neck disappeared soon after drilling of the femoral neck and head.

Drilling has the disadvantage of a prolonged post-operative course lasting from 9 to 12 months. Walking without weight bearing on the affected extremity may cause slipping of the femoral capital epiphysis of the normal side.

With internal fixation by means of the Smith Petersen nail, full weight bearing is possible after from 9 to 12 weeks. Fusion of the femoral capital epiphysis occurred at about 12 weeks without any evidence of secondary slipping of the epiphysis.

GEORGE L. RENZI, M.D.

Indications and Technique of Surgical Treatment of Post Traumatic Genu Recurvatum (Indicazioni tecniche nella cura chirurgica del ginocchio recurvato post traumatico) LEONARDO GUI *Chir. org. modern.* 947 3 53.

Observations on 5 patients with post traumatic genu recurvatum led the author to believe that Lange's simple osteotomy furnishes very satisfactory results if the operation is performed by a competent orthopedic surgeon. The main objection to the operation, namely the difficulty in estimating the degree of angulation to be employed after the operation can be overcome by the following technique.

Roentgen pictures are taken in lateral direction with the knee in hyperextension. An incision from 8

to 10 cm. is made on the lateral aspect of the lower third of the thigh and a linear osteotomy perpendicular to the axis of the femur, is done approximately 4 to 5 cm. above the condyles. Roentgenograms are taken in lateral direction. A comparison with films taken before the operation permits a calculation of the necessary degree of angulation. Deviations, if any in regard to varus or valgus positions, or rotation are corrected. The wound is sutured and a cast is applied. After a month the cast is replaced by a new one. The patient is kept in a cast for from 2 to 4 months according to the evidence of consolidation of the fragments. Bier's hyperemia massage (faradic current and mechanotherapy) are employed.

The main indication for the operation is given by a fracture through the diaphysis of the femur with angulation in the sagittal plane. An osteotomy of a fractured tibia should never be done because of the danger of pseudarthrosis. JOSEPH K. NARAY, M.D.

Observations on the Management of Suppurative Arthritis of the Knee Joint. OSCAR P. HANSTON, *J. Am. J. Surg.* 947 74 631

Significant changes in the management of suppurative arthritis of the knee developed out of the experiences in the Mediterranean Theater during World War II. Knee joint wounds are serious not only because of their threat to normal function but also because of their potential threat to life and limb. The death and amputation rates from knee joint sepsis in World War I were high and so great was the respect of the French for the sequelae of this injury that they employed primary resection prophylactically in severely damaged joints and secondary resection when the suppurative arthritis did not respond promptly to drainage and immobilization.

Suppurative arthritis is potential in every penetrating wound of the knee joint, but sepsis is established only when, after several days, there is decomposition of the tissues and formation of pus. Management begins with wide arthrotomy for complete inspection of the joint, removal of all foreign bodies and devitalized tissues, thorough irrigation of the joint, and closure of the synovia. Complete immobilization in a plaster spica or a Tobruk splint plus local and systemic penicillin therapy completed the regimen that held the occurrence of sepsis to a low rate. Failure through loss of tissue or time lag to close the synovia resulted in slow healing and disproportionately great scarring and limitation of motion. Eventually for this reason, closure was done 24 hours or more later. It was observed that the incidence of established suppurative arthritis varied with the extent of damage to the joint and the adequacy of excisional surgery. Resection of the joint was not considered even though prolonged suppuration with joint destruction was likely.

Therapy of an established suppurative process consisted of wide parapatellar incisions for continuous drainage, immobilization, and administration of antibiotics. Slow destruction of the joint and concurrent

Fig. 1

Fig. 2. Photograph of the medial arthrotomy incision. Inflamed synovial membrane and the partially necrotic cartilage of the comminuted patella are poorly visualized.

chronic sepsis in many instances suggested the need for a more satisfactory mode of treatment. Continuous drainage incisions are inefficient in preventing bacterial cartilage digestion and impair the antitoxin continues as long as any devitalized cartilage remains and secondary invaders readily gain foothold where the articular cartilage nutrition is impaired. It appeared then that continuous drainage of the knee joint was contraindicated and therapy of established suppurative arthritis should be based on

Fig. 2

The small piece of woollen cloth is shown on the gauze at the left of the incision. The quadriceps pouch was filled with a coagulated fibrinous exudate.

Fig. 3. Following removal of the patella and cleansing of the joint, the synovial membrane of the arthrotomy incision and the defect in the old wound were sutured (plus a few sutures in the tendon). The joint was filled with penicillin.

Fig. 3

the same principles as the management of potential infection

The revised therapy provided that, regardless of the time lag or duration of sepsis the joint cavity must be exposed fully and all foreign bodies and devitalized tissue excised. Clots and exudate are removed, and the synovia closed if necessary are replaced graft or rotated skin flap. Penicillin solution is instilled into the joint, thorough immobilization provided and systemic penicillin therapy instituted. The reaccumulation of joint fluid is aspirated through

the windowed cast with the instillation of penicillin, at 24 to 48 hour intervals. When the danger of continuing sepsis is past (5 to 7 days) the remaining soft parts are sutured. When they are sufficiently healed or at about 5 weeks postarthrotomy a Thomas splint with Pierson attachment replaces the plaster spica, and passive motion is gradually increased.

This regimen was most successful in reducing morbidity and securing maximum function. When the tissue loss was so great that subsequent joint function was precluded, sepsis was eliminated and the optimum result was obtained by joint resection. The bone ends were held in apposition firmly to eliminate dead space.

Excellent case reports demonstrate the effectiveness of penicillin only in the presence of adequate surgery with removal of all devitalized tissue, and the possibility of salvaging a joint if intra-articular foci are excised before the digestion of undamaged articular cartilage begins. One case of knee joint resection in the face of severe sepsis was resorted to instead of amputation (one leg was already amputated) in order to save life.

It is reasonable to suppose that blood borne suppurative arthritis of the knee not responding to aspiration immobilization, and antibiotics, would like wise yield to excision of sepsis-devitalized tissue, exudate and hematoma, with closure of the synovia and the regimen so satisfactorily evolved in the handling of these war wounded joints.

FRANCIS E. DEERBECKER, M.D.

FRACTURES AND DISLOCATIONS

Use of Internal Fixation in Compound Fractures.
BA NARA B. SINGH. *Am J S* 2: 1947 74 697

The author has made an analysis of compound fractures of the shaft of the femur and tibia which were treated on a fracture service during the years 1935 through 1942. There were no cases of nonunion among patients in whom the fixation was rigid. There were minor disasters such as broken plates and refractures, but none that jeopardized life or limb. (The metal itself does not introduce bacteria nor does it provide a medium for their growth.) An adequate length of plate and one or more transfixation screws to prevent torsion strain were necessary. Rigidity is therefore, the first principle underlying the use of internal fixation in the treatment of compound fractures.

The initial treatment of compound wounds is surgical débridement and copious lavage with water or saline. From 1935 through 1942 all wounds were left open, with sutures placed but not tied. In 1945 some of the wounds were closed initially.

The end-results in 15 fractures treated by internal fixation and initial closure are tabulated. The use of penicillin and other antibiotics permits the surgeon to sleep better at night, but replaces neither careful surgery nor mechanical principles. Amputation was necessary in but one case due to inadequate débridement and tight closure. The follow-up results for a

period of 5 years or more are shown. Among 37 cases of compound fracture there were 2 deaths due to other causes, and 3 amputations in patients who could not be followed.

The late results in 14 cases of war injuries to the femur and tibia are included. Operations were performed at intervals varying from 3 days to 6 weeks after wounding. There were no deaths, no amputations, and no case in which there was spread of infection or nonunion. All wounds were solidly healed. Five men with compound fractures of the tibia are employed and 3 others have limitation of knee motion.

The author believes that certain compound fractures of the lower extremity should be plated and emphasizes the necessity for correct surgical treatment of the wound without initial skin closure followed by adequate suture under anesthesia after a period of 5 days and rigid mechanical fixation of the fracture.

RICHARD J. BARNETT, Jr. M.D.

Cortical Fixation (Ober Corticalbohrung). T. JOHNS.
Brit J Chir 1947 34 332.

Because of the danger of fat embolism associated with fixation material passing through the bone marrow the author has attempted to provide fracture fixation by means of support placed in the cortex without injury to the marrow. The best results followed the use of thin rectangular metal plates which were driven into a slot made in the cortex by a circular saw. The fracture was freely exposed, reduced, and then held in position by elevators or clamps while a slot was cut in the longitudinal axis of the fragments. In order that the metal plate could be more easily driven into the slot, its lower edge was beveled. For firmer fixation the thickness of the plate was slightly greater than that of the saw and its flat surfaces were grooved (Fig. 1). It is surprising how firmly a fracture is held by this simple method both with respect to transverse shearing movements and to rotation.

The author has used the method in 5 cases. In one case of fracture of both bones of the forearm the plates became loose and worked out of the slots so that a pseudoarthrosis was present at the end of 5 months. Union was obtained by a bone grafting operation. This result might have been avoided if the plates had been held in place for a longer time by means of wires encircling the bones. In the future the author plans to fix the plates by the use of wires when prolonged fixation appears necessary. For the larger bones (femur, humerus, tibia) or even 3 plates may be advisable. By placing the saw cuts parallel or at an angle to one another one might achieve maximum stability in one or in several directions (Fig. 2).

Experiments indicate that this method of cortical fixation prevents transverse and rotational movements, but it has certain disadvantages with respect to operative damage to the periosteum and with respect to bending strains.

Fig 1 (Johner)

The Recurrent Dislocation of the Shoulder (Ueber die habituelle Schulterverletzung) ARNOVON HELLENHANS
Ann. chir. gymn. 1947 36 Supp. 3.

There are certain anatomical changes which predispose a shoulder joint to recurrent dislocation and which are found following the first dislocation. There may be a general stretching of the entire capsule which makes it possible for the humeral head to dislocate intracapsularly. The capsule may show a pocketlike herniation or there may be an actual tear in the capsule. Perthes was first to call attention to the frequent occurrence of a capsular defect in the region of the labrum glenoidale. Hybenette found a large number of cases with a slit type of tear about 2 c.c. long in the anterosuperior portion of the capsule underneath the subscapularis muscle. Less frequently there was a separation of the entire labrum glenoidale. Not infrequently there was a tear of the infraspinatus and supraspinatus muscles at the greater tubercle associated with a tear in the capsule.

Bankart and Gray stated that a tear of the labrum glenoidale alone was the cause of recurrent dislocation of the shoulder. Laugenakjold supported this view and added that when the tear occurred in the capsule without injuring the labrum healing usually occurred and recurrent dislocation never resulted.

Often changes were observed in the humeral head. There was either a fracture of the greater tubercle or there was a wedge shaped defect in the posterolateral aspect of the humeral head (en hachette). Occasionally the mechanism of the injury predetermined whether there would be a recurrent or simple type of dislocation. Bankart found that a fall directly on the shoulder or on the elbow pushing the humeral head forward usually injured the labrum glenoidale and resulted in a recurrent type of dislocation.

Fig 2 (Johner)

ation. An injury in which the head was levered out of the glenoid fossa caused a simple type of dislocation.

A congenitally relaxed capsule inco-ordination of the shoulder muscles, and abnormally short pectoralis or latissimus dorsi muscles were cited as factors predisposing to recurrent dislocation of the shoulder joint. It is significant that dislocations of the shoulder scapular joint occur frequently in young individuals and epileptics.

Many workers advocate early mobilization and just as many advise early mobilization as the best treatment of acute dislocation of the shoulder.

There are more than 30 operative procedures recommended for the repair of recurrent dislocation of the shoulder joint. The conservative measures have only historical significance. There are two main groups of operations: (1) the arthrodesing operations which have little practical value and (2) the operations in which the joint components are preserved. Operations on the capsule and adjacent muscles include capsulorrhaphy without opening of the joint and reinforcement of the capsule with fascial free fascia lata transplantation and transfer of tibial periosteum for reinforcement of capsule defects. Magnusson uses portions of the subscapularis to reinforce the shoulder capsule. Repair of the labrum glenoidale is advocated by Bankart.

Clairmont and Ehrlich introduced a repair which portions of the deltoid muscle are placed underneath the capsule and sutured posteriorly in the lateral compartment of the axilla. There are many modifications of this procedure.

In 1914 Kirschner used a suspension operation the first time by threading a strip of fascia through the humeral head and through the acromioclavicular joint.

In 1927 Carrel used a similar procedure employing the long head of the biceps. Henderson modified the Loeffler operation by using the peroneus longus muscle to suspend the greater tubercle from the acromion.

Heymanovitch threaded the long head of the biceps through a channel that was artificially constructed under the intertubercular canal. He modified this procedure 3 years later (1929) by directing the artificial channel from the distal end of the intertubercular sulcus into the center of the articulating surface of the humeral head. Nicola described the same procedure a few years later without knowing of Heymanovitch's publication. Experiments carried out in rabbits have shown that the transposed tendon deteriorates very quickly and disappears completely in a great many instances. Other workers have used silver wire and silk to suspend the humeral head on the acromion.

Finally there is a group of operations which involve the bones which make up the shoulder joint. Osteotomy of the humerus at the level of the surgical neck is not very successful. Eden Hybenette devised a procedure in which a bone transplant taken from the tibia or the iliac crest is placed anteriorly to the humeroscapular joint. It protrudes medially for a distance of from 1 to 1.5 cm. from the glenoid rim and prevents the humeral head from dislocating anteriorly. The complication most frequently seen following this procedure has been degenerative arthritis. Orell suggested the use of os purum for the anterior bone block.

The best results were obtained by the Bankart operation. Several surgeons used this procedure in 90 cases and reported only 1 recurrence. The Eden Hybenette operation was used in 303 cases by several different surgeons and 3 recurrences were reported. The Heymanovitch-Nicola operation was used in 387 cases with 34 recurrences. The poorest results were obtained by the suspension operation after which recurrences were reported in 33 per cent of the cases.

The author further analyzed 164 operations and illustrated his remarks with roentgenograms, diagrams, arthrograms and detailed tables.

GEORGE I. REISS, M.D.

New Operative Technique for Recurrent Anterior Dislocation of the Shoulder (Nueva técnica operatoria para la luxación recidivante del hombro h. de adelante) ANTONIO BORILLINI *Rev. chir. bra.* 1941, 8, Abr. 947-63

A new method of treating recurrent dislocation of the shoulder is described by the author. A slightly curved incision along the deltopectoral groove or a T-shaped incision, or an incision in the form of an inverted L is employed.

The apex of the coracoid process with attachment of the tendons of the short portion of the biceps, the coracobrachial and the pectoralis minor muscles are separated from the remaining portion of the bone care being taken not to injure the musculocutaneous

nerve or its branches. The detached fragment of the coracoid process is carried underneath the deltoid muscle and is attached by means of catgut sutures to the acromion. The corresponding arm is placed in abduction of from 60 to 70° moderate antelposition and intermediate rotation, to facilitate the procedure.

The arm is immobilized for 30 days and after that treated with heat, massages, and active and passive motion.

The postoperative condition in 3 cases was very satisfactory but the period of observation is too short to allow definite conclusions as to the permanency of the results. JOSEPH K. NARAT, M.D.

Complications of Fractures of the Lower End of the Radius (Complicaciones de las fracturas de la extremidad inferior del radio) JOSÉ BRAVO and DIÁZ-CARRERO. *Ciruj. aperi.* 1941, 4, 117

Of 66 patients with fractures of the lower end of the radius, 10 presented complications: stiffness of the wrist and fingers in 5, compound fractures in 5, fracture-dislocation in 6, aseptic necrosis in 3, and Sudeck's atrophy in 3.

Among the late complications of fractures of the lower end of the radius, the following are mentioned by the author: contractures, recurrent tenosynovitis, neuritis, osseous atrophy, cysts of the bone and aseptic necrosis. JOSEPH K. NARAT, M.D.

Mechanism of Fracture of the Carpal Scaphoid (Mecanismo de fractura del escafoides carpiano) HÉCTOR DAL LAGO. *Rev. As. méd. argen.*, 1941, 6, 103.

The author presents a theory of the mechanism of fracture of the proximal extremity of the scaphoid which is in accord with the anatomic and roentgenographic facts observed in hyperextension of the wrist. He shows that in this movement an arch is formed by the trapezium, trapezoid, scaphoid, semilunar, capitate, and pisiform of which the trapezium constitutes the basic point of support when the hand is in contact with the ground. The concavity of this arch surrounds the os magnum which thus remains suspended and away from the ground being separated from the latter by the entire content of the carpal canal. When a subject falls on the hand in hyperextension, two convergent forces act on the wrist. One starts from the point of support (trapezium) on the ground through the thenar eminence and is transmitted by the vertical column of the trapezium-scaphoid-radius in an upward direction. The other (counter-coup) descends through the radius toward the carpus where it divides into two forces: one that continues through the scaphoid where it meets the ring force and may produce fracture of the bone by simple closure of its frontal angle, and another which continues through the semilunar, os magnum, and third metacarpal. As the scaphoid does not meet with any support above in its external radial portion and the os magnum is not supported from below, a torsion couple is formed which frac-

tures the scaphoid at the point where these two forces come together. The combination of the two actions that of compression and that of torsion clarifies the mechanism of all fractures of the scaphoid no matter where they occur as it explains how the radial or cubital inclination, by changing the point of support of the styloid apophysis on the scaphoid changes the location of the point of torsion of the couple.

The scaphoid may be subjected to various traumatic influences the results of which may be classified as follows (1) fractures from a direct blow (2) indirect fractures (a) from divulsion of the tuberosity through ligamentary action (b) from closure of the frontal or sagittal angle, but it would seem that in opposition to the concepts of Deatott and Delbet the angle that closes is not the sagittal but the frontal, (c) from divergent compression or strangulation of the body of the bone through formation of a torsion couple (author's theory) (d) from opening of the sagittal angle this being the type of fracture that accompanies dislocation of the semi-lunar bone.

RICHARD KREML, M.D.

Injuries to the Hip Joint. Traumatic Dislocations Incurred Chiefly in Jeep Accidents in World War II. MARSHALL R. URSAT. *Am. J. Surg.*, 1947 74 586.

The author's report (the first of a series of three presenting an analysis of 58 hip joint injuries in United States Army hospitals in the European Theatre from 1944 to 1946) concerns 15 cases of simple dislocation of the hip. In one case the dislocation was anterior (obturator) and in 14 cases the dislocations were posterior and most of them were sustained in jeep accidents.

The construction of the jeep plus high speed driving provided almost ideal circumstances for producing dislocated hips in the event of head-on crashes. The low seats require rather acute flexion of the passengers' hips, bringing the knees close to the dash board and the lack of enclosure facilitates their falling out on side or back. The riders' position at the time of accident is nicely correlated with the nature of his injury and illustrated by sketches.

Damage in this series of cases is chiefly to the soft parts of the joint but in post reduction films of good technical quality minor fractures are demonstrable, i.e. incomplete fissures of the posterior acetabular rim or avulsed chips in the line of capsular attachment to the acetabular or trochanteric regions. The probability of damage to the capsular vessels in the latter type of injury is considerable but avascular necrosis of the femoral head did not complicate any of the cases in this group.

These dislocations were recognized and reduced fairly easily by relatively inexperienced surgeons. The Stimson technique was successfully used in half of the cases and is recommended for first attempts to reduce any posterior dislocation. Post reduction traction was employed for from 4 to 8 weeks (about 6 weeks was considered optimum) for joint structure healing. Weight bearing was initiated at from 3

months on although all of these patients had been instructed not to bear weight for a period of 6 months.

At a two year follow up 9 of the 15 patients were located. They are compared with 7 civilian patients from the Massachusetts General Hospital Boston, 1 to 7 years after their injuries. The longer period of traction and delayed nonweight bearing in the military patients produced no results superior to those in the comparable civilian patients who had been treated with much shorter immobilisation and earlier crutch walking.

FRANCES E. BREWSTER, M.D.

Slipped Epiphysis in the Adolescent Hip. A Reconsideration of Open Reduction. PAUL H. MARSH. *J. Bone Surg.* 1948, 30-A, 9.

The results of open reduction in the treatment of minimal degrees of slipping are uniformly good however the results are poor in a large number of cases of severe or complete slipping of the epiphysis. Early reduction of the slipped epiphysis is suggested. Traumatic arthritis is a late secondary result of ischemic necrosis of the capital epiphysis and the cause of most of the poor results in any reduction treatment, open or closed. Gross aseptic necrosis seldom occurs in untreated cases. Many excellent reductions of a displaced epiphysis are followed by necrotic changes. Preservation of the blood supply to the epiphysis is the crux of the problem of treatment. The blood supply to the capital epiphysis of the femur comes from (1) a few small vessels which penetrate the cartilage plate from the neck (2) the vessels in the ligamentum teres and (3) the vessels in the perosteum of the neck. The blood supply of the epiphysis is meager after slipping occurs.

During the last 7 years the author has observed and treated, by various methods 26 patients (33 hips) with slipping of the capital epiphysis. His conclusions are the result of that experience.

The injudicious manipulation in closed reduction and surgical trauma in open reduction have been the sources of most of the difficulty. Closed reduction should be condemned except for gentle manipulation to reduce an acute displacement. In cases in which open reduction is required great care should be taken to preserve both the ligamentum teres and the perosteum on the posterior and inferior surfaces of the neck and the epiphysis should not be entirely detached from the neck in this region. Due to this careful operative consideration the head should survive. If the displacement of the epiphysis is more than 1 cm either downward or posteriorly reduction is necessary. If symptoms have not been present for more than 2 weeks reduction by manipulation may be tried. Often reduction may be accomplished by gentle traction and internal rotation followed by or combined with abduction. If the epiphysis can be reduced easily it should immediately be fixed by a Smith Petersen nail.

The operation is described in detail and the incisions into the hip joint and into the femoral neck are explained. Sufficient bone should be removed.

the anterior and superior aspects of the neck to allow the neck to be easily reduced into the head and care must be taken to avoid tearing or even excessive tension on the posterior and inferior peroneal vessels. After the epiphysis has been re-aligned it is fixed by a Smith Petersen nail. The author has used this method in 8 cases since 1913. In 7 cases an average of 21 months' time has elapsed since operation and in 6 of the 7 patients the results were excellent. The operation is difficult, and the technique is exacting and tedious. Several figures, roentgenograms, photographs of patients, and drawings of the operative technique are included.

RICHARD J. BENOETT, JR., M.D.

The Management of Battle-Incurred Compound Fractures in the Region of the Hip Joint. MASHALL R. UHRY, M.D. *Surgeon* 1947 101:467

This article presents the experience and end-results of treating 29 personally observed battle-incurred fractures in the region of the hip joint, in which the follow-up extended from 6 months to 2 years. It includes a table showing the classification of the hip fractures and associated injuries and operations. A plan of management for wounds in the region of the hip joint is proposed based upon the experience obtained in this series of cases. The treatment should consist of débridement, arthrotomy and exploration of the hip joint, and irrigation if gross suppuration is not present. Primary closure of the joint is performed if loss of substance does not make it impossible. This procedure should be carried out as soon as possible after wounding. Chemotherapy should be used to the limit of its usefulness. This procedure should be carried out even in the presence of sepsis.

The surgeon's judgment must determine the amount of débridement of the tissues. The skin should be left open and closed later by delayed suture, and the extremities should be extended and suspended for from 8 to 12 weeks. Active motion should be begun as early as possible.

Whole blood should be used in liberal amounts, and other supportive measures should be employed in some selected cases after successful secondary suture of the wound. Avascular necrosis of the head of the femur probably increases the susceptibility to infection. When necrosis occurs, the dead bone thus serves as a possible focus of infection.

Associated perforations of the bowel most often lead to pyarthrosis, but associated perforations of the bladder are not responsible for subsequent suppurative arthritis. The prognosis in this type of injury is considerably more favorable if the fracture occurs at or below the intertrochanteric area.

The methods of management employed in the treatment of these cases is described in detail in the treatment of 9 cases. Chemotherapy for septic joints has not been found to be effective without preliminary radical surgery. The author believes that failures of judgment in hip joint surgery have been due to conservatism rather than to overzealous surgery.

RICHARD J. BENOETT, JR., M.D.

The Treatment of Pseudarthrosis of the Femoral Neck (Zur Behandlung der Schenkelhalspseudarthrose) O. SCHÜRER and H. BAUTSCH. *Helv. chir. acta* 1947 14:405.

The advantages of the extra-articular operation in recent fractures of the femoral neck suggested the employment of the same procedure in the treatment of pseudarthrosis in the same location. Eighteen operations were performed by the author on 16 patients. 13 of the patients remaining under observation from 2 to 8 years. The use of the 3 flanged nail was combined in some instances with a bone graft. In such cases the nail was placed cephalad and the apofyseal graft from the fibula close to the distal portion of the femoral neck. The intra-articular location of the graft in the region of the caudal portion of the neck did not provoke any functional disturbances. The broad flanges of the nail may inhibit the advance of new blood vessels from the caudal portion of the neck, and therefore the author prefers to place the nail above and the graft below.

Whenever a bone graft was employed for osteosynthesis the patient was kept in a body cast for a period not exceeding 3 months, but was allowed to walk on crutches.

An osseous union was obtained in all of the patients but one. The functional results were very satisfactory. Only in complicated cases was the nailing combined with a bone graft. Hence, the author is not in a position to discuss the merits of both methods. Two or even three grafts may not be able to prevent a slipping of the united bony fragments, and therefore the use of a nail in addition to the graft seems advantageous.

Necrosis of the femoral head occurred in 6 instances and necessitated removal of the nail.

An extra-articular arthrodesis is employed by the author when the pseudarthrosis is of long duration and the secondary changes are marked.

JOSEPH K. NARAY, M.D.

Brackett Operation for Ununited Fracture of the Neck of the Femur. JOHN C. LYNN and RALPH K. GROOMLEY. *Surgey* 1947 2:89.

The need for careful collection and study of end results obtained with the various operative procedures designed for the restoration of function in ununited fractures of the femoral neck continues. As an aid in this study a well-defined set of criteria should be adopted to standardize the evaluation of end-results by different authors.

At the Mayo Clinic the Brackett operation or the procedure as modified by Magnusson was used in 71 cases of nonunion after fracture of the femoral neck, in the years from 1920 to 1945 inclusive. Good results were obtained in 66.7 per cent of the 63 cases in which evaluation was possible.

Internal fixation by means of beef bone screws, or metallic nails or screws was used in 53 of the 71 cases, and good results were obtained in 35 cases. In 4 of these 55 cases follow-up data were not adequate to allow evaluation.

Proper selection of cases careful operative work, valgus position of the femoral head on the remodeled shaft, and adequate internal fixation are important in this operation.

Treatment of Fractures of the Os Calcis by Open Reduction and Internal Fixation ALFRED H. WHITTAKER. *Am. J. Surg.* 1947 74: 687

The author discusses the anatomy of fractures of the os calcis and the high percentage of resultant permanent partial disabilities. The evolution in the treatment of fractures of the os calcis is discussed and an operation is described whereby open reduction makes possible direct manipulation of the fragments. The author suggests that this realignment of the fragments cannot be carried out by closed reduction because the cortical bone is dislocated and cannot be brought back into place accurately. The author uses a curved medial incision because the interposition of the fragments occurs in this area. It is also on the medial side that displacement of the articular surface of the subtarsal joint can be seen. The abductor hallucis muscle may be avulsed with a fragment of bone. The rotated and interposed fragment of the cortical bone is removed by grasping the tuberosity with bone-holding forceps, the line of the tuber angle restored. Drill holes are made across the line of fracture and screws inserted. The abductor hallucis muscle which is attached to an avulsed fragment is replaced and held by screws or sutures.

The end results show that it has been possible to obtain an anatomic reposition and healing at a normal rate. The first patient operated upon had a severely comminuted fracture with marked displacement and extensive involvement of the subtarsal joint. This patient was walking well at 4 months and at the end of the year presented complete recovery with no disability. Two other patients recently operated upon are walking and have excellent anatomic reposition. Sufficient time has not elapsed in these cases to determine whether or not traumatic arthritis will develop.

RICHARD J. BENNETT JR., M.D.

The Mechanism and Treatment of Fractures of the Calcaneus. Open Reduction with the Use of Cancellous Grafts. IVAR PALMER. *J. Bone Surg.* 1948 30-A: 2

The accepted theory of the mechanism of fractures of the calcaneus is investigated in the light of experience gained in surgical exposure of the fragments. The vertical shearing force which splits the calcaneus and produces only a simple linear fracture presents no difficulty in mechanism or in the treatment of the fracture toward a favorable prognosis. In addition at least 50 per cent of all calcaneal fractures present a further problem—intra-articular involvement—produce a ledge of up to 10 mm. height between the levels of the joint surfaces of the two fragments.

Equally often the upper fragment extended posteriorly to include the upper part of the tuber calcanei and the two portions of the bone gaped posteriorly.

Special roentgenograms are necessary to determine the nature of the fracture and for the selection of special cases requiring open reduction. The opinion of the roentgenologist is necessary in order to judge (1) whether a simple linear or a linear and compression fracture is present, and (2) if comminution and depressed articular fragment and the depth of its depression below the rest of the articular surface.

Transfusion and traction as well as subcutaneous exploration showed that the depressed fragment was firm and stable and could be levered up to restore the continuity of the articular facet. Only a moderate exposure was necessary to accomplish this result when traction was maintained to reduce the lateral block. An iliac bone graft cut to snugly fit the lateral articular defect firmly locks the reduction in place. A plaster boot without transfixing pins maintains the immobilization and nonweight bearing ambulation is permitted several days postoperatively. After a period of 12 weeks gradual weight bearing in a firm shoe with metal arch support is begun.

Twenty three patients so treated were all back at work in from 4 to 8 months after operation and the majority of patients have shown one fourth to one half normal painless pronation supination. In all patients, the shape of the longitudinal arch is the same as that in the uninjured foot. This is in strong contrast to the situation in patients treated conservatively.

FRANCIS E. BRECKENRIDGE, M.D.

ORTHOPEDICS IN GENERAL

Osteoporosis. FULLER ALBRIGHT. *Ann. Int. Med.* 1947 27: 861

The author defines osteoporosis as a disturbance in the metabolism resulting in decreased production of osteoid by the osteoblasts. The uncalcified matrix is termed osteoid. The osteoblasts which lay down the osteoid become enmeshed in it as osteocytes. It is believed that phosphatase or phosphorilase or both, are active in splitting off the inorganic phosphate from organic phosphate compounds and the precipitation of a calcium-phosphate-carbonate salt called dahlite. Osteoporosis is a disorder of tissue metabolism rather than of calcium phosphorus metabolism. It must be differentiated from osteomalacia and from osteitis fibrosa generalisata. Osteomalacia is produced by a disturbance in the calcification of the osteoid and osteitis fibrosa generalisata is produced by an increased bone destruction.

In the elderly person that is a woman of 60 or a man of 80 there seems to be a decrease in the bone mass due to a decrease in bone formation (anabolism) rather than increased bone destruction (catabolism). Certain steroidal hormones affect osteoblastic activity. The ovarian hormones (estrogen and progesterone)

the testicular (androgen) and the adrenal cortical nitrogen hormone stimulate osteoblastic activity. The adrenal cortical sugar hormone inhibits these anabolism. The ovarian hormones appear at the menarche and disappear at the menopause. Androgen, produced by the interstitial cells of Leydig, appears at puberty and is present normally until very late in life (80 plus years). The adrenocortical N hormone also appears at puberty and ceases at the time of the 'adrenopause' at from 80 to 90 years. The adrenocortical S-hormone is apparently present throughout life.

According to Albright the causes of osteoporosis are (1) lack of skeletal stress and strain (2) lack of nitrogenous building blocks (3) steroid hormone imbalances.

Skeletal stress and strain is the greatest single stimulus to osteoblastic activity. If this is lacking a disuse atrophy develops. In senile osteoporosis, not only is there a steroid hormone imbalance, but there is also an element of disuse atrophy particularly if the patient is overprotected.

Lack of nitrogenous substances used in building osteoid is seen in starvation, in malnutrition and in nephrosis. Serum albumen is believed to be the most important nitrogenous substance.

In old age, bone atrophy is part of the picture of generalized tissue atrophy. It is partly at least, due to decreased production of anabolic steroids (estrogens and androgens) in the presence of continued production of anti-anabolic steroids (adrenal cortical S-hormone) and the atrophy of old age does respond to steroid therapy.

Since estrin has a marked effect in stimulating osteoblasts, when it is no longer produced (after the menopause) osteoporosis results. The menopause is relatively early in females and accounts for the higher incidence of osteoporosis in that sex.

Cushing's syndrome, the adaptation syndrome of Selye and the administration of adrenocortical trophic hormone are conditions characterized by an excess amount of anti-anabolic steroid (adrenocortical S-hormone). VERNON C. TORRES, M.D.

Orthopedic Treatment of Certain Deformities of Extraparavertebral Origin (Trattamento ortopedico di alcune deformità d'origine extraparavertebrale)

CARLO FAINI. *Chir. org. movim.* 1947 3 37

The multiform dystonia of posture rarely comes under the direct observation of an orthopedist because it belongs in the domain of neurology. Moreover an orthopedist is apt to misinterpret the deformity unless he is familiar with the extrapyramidal syndrome.

The polymorphism of symptoms and the various theories of the pathogenesis of the condition are responsible for the multiplicity of terms, such as torsion spasm, tonic neurosis of torsion progressive lordotic dysbasia, deforming muscular dystonia, lenticular dystonia, dystonia of torsion and dystonia of posture. The author favors the last mentioned term because the clinical manifestations are not

always limited to a torsion or lordosis of the trunk, and because the name does not suggest any pathogenesis which remains obscure.

Dystonia of posture is a syndrome which most frequently is the sequel of epidemic encephalitis but may also be caused by Wilson's disease, Westphal-Stroempell's pseudosclerosis, or chorea. The generic term of dystonia of posture applies to modifications caused by disturbances of the tones of skeletal muscles whose function is to maintain equilibrium of the body in standing. The dystonia is attributable not to paralysis or amyotrophy of any muscles but to degenerative changes in the corpus striatum, pallidum, internal capsule, or black substance of the frontal lobe. Hyperkinesia or dyskinesia of the choreoathetoid type may be combined with alterations of posture.

A study of cases convinced the author that a prothesis furnishes excellent results if the condition completely disappears in recumbent position and is not complicated by choreoathetotic movements. Braces offer several advantages over plaster of Paris casts. They allow application of physical therapy and a gradual correction of posture. Rapid correction, necessary when a cast is used is highly undesirable. Finally the brace can be applied in the recumbent position when the deformity is not manifest. However the beneficial effect of a brace cannot be ascribed solely to the passive correction. Normal posture and gait are maintained by a complex of proprioceptive reflexes. A deviation of such reflexes, created by a lesion of the extrapyramidal centers and paths, leads to a dystonia of posture. A prothesis minimizes the abnormal afferent impulses and enhances the regulation of the proprioceptive regulatory mechanism. JOSEPH K. NAKAT, M.D.

Orthopedic Operative Procedures Allowing Early Motion. FRANK E. STURGEONFIELD. *Arch. Surg.* 1947 55 650.

Various new orthopedic procedures have replaced older operations with the aim of allowing early mobilization of the affected parts. Acromioclavicular separations are treated by the insertion of Kirschner wire through the acromion into the lateral aspect of the clavicle. This allows early motion of the shoulder and arm.

Removal of the radial head is recommended to allow early motion of the elbow while early evacuation of the hematoma allegedly prevents myositis ossificans in the brachialis muscle. These findings are based on an unknown number of patients who did not develop myositis ossificans, while prior to the advent of this procedure, this complication was found in about 10 per cent of the patients.

In all fractures of the metacarpal bones, with the exception of fractures of the first metacarpal bone, immobilization by means of Kirschner wires is recommended. The wires are cut close to the skin surface and the skin is allowed to close over the wire ends. Immediate motion of the fingers and wrist is possible and encouraged.

Intertrochanteric fractures are treated by insertion of a Smith Petersen nail with a McLaughlin plate which allows for varus or valgus deformity of the femur. Prior to the introduction of the operative procedure an intertrochanteric fracture was considered to be a much more difficult fracture to treat satisfactorily than the transcervical fracture.

In fractures of the femur a Kuntscher nail is inserted into the medullary cavity of the femur through the greater trochanter. Ambulation on crutches is possible 2 weeks after the operation and crutches is effected 7 months postoperatively.

Internal fixation with plate and screws and transfixion screw at the fracture site is employed in fractures of the tibia. The extremity is suspended in a Thomas splint and Pearson attachment. The patient is allowed to be ambulatory as soon as the sutures have been removed.

In reference to fractures about the ankle the author presents roentgenograms of a bimalleolar fracture dislocation of an ankle. A tibial and fibular bone plate with screws and two transfixion screws are used for internal fixation. With this method bony union of the soft parts about the ankle is presumably prevented.

In the treatment of Achilles tendon and patellar tendon tears the author employs a modified Bunnell pull out wire suture technique. The patient is allowed to walk with an Unna's boot 2 weeks after the operation. The wire and the bolt through the os calcis are removed 6 weeks after the operation.

The author points out that in fusion of the fifth lumbar vertebra to the sacrum a bone chip is inserted into the lumbosacral facets and a screw is driven through the facets. This procedure makes it unnecessary for the patient to remain in bed longer than 12 days postoperatively and he is allowed to walk with the support of a Knight spinal brace. In fusion of the fourth and fifth vertebrae however the patient is kept in bed for 6 weeks.

GEORGE I. REISE, M.D.

Bone Grafts. An End Result Study of the Healing Time. W. A. BURKH JR., RICHARD C. STAUFFER, and ALVIN L. SWENSON. *J. Bone Surg.* 1947 29 901.

The authors have studied the healing time in 358 of 580 bone grafts which came under their observation.

There were 40 failures (11.2%). The remaining 318 cases comprised 34 iliac grafts with an average healing time of 27 weeks, 121 iliac grafts with an average time of union of 20 weeks and 163 iliac type grafts with an average time of union of 19 weeks. Delayed union beyond the sixteenth week occurred in 180 grafts, namely 51 iliac (28.4%), 70 iliac (57.8%) and 79 dual type grafts (48.4%).

Plates were used in conjunction with 3 iliac grafts, 23 iliac grafts, and 12 dual grafts. The healing time was the same with or without use of the plate. There were no postoperative fractures in this group of cases and early mobilization was possible in all instances. Adequate fixation of the graft with screws permits

early mobilization of adjacent joints. The authors state that this method of treatment resulted in a marked reduction of the length of the convalescent period and the degree of permanent disability was often reduced.

Onlay grafts were preferred for use in the cases of uncomplicated nonunion of long bones. Dual grafts were used to bridge defects to repair nonunion near a joint or in cases in which there was marked decalcification or sclerosis or in which a previous bone graft had failed.

In their preparation of the bed for reception of the graft, the authors favor removal of at least two-thirds of the thickness of the cortex. Short grafts are seldom if ever indicated. Rigid fixation of the graft is mandatory.

DANIEL H. LEVINTHAL, M.D.

Painful Amputation Stumps (Les moignons douloureux des membres). P. PADOVANI and L. MANSUETI. *J. chir. Par.* 1947 93 527.

The authors summarize their report on amputation stumps to the Fifteenth Congress of the Association Française de Chirurgie which is based on a review of the French and foreign literature and a study of the wounded in the French Federation of Amputees as well as on personal communications. The clinical types of stump pain are enumerated. For proper diagnosis of the cause of the pain, a meticulous anamnesis and careful general and local examination roentgen examination and a study of the arterial circulation including arteriography are needed. A discussion follows of the pathologic physiology involved in the constituent elements of the stump ascending paths of pain conduction as well as the sympathetic nervous system and cerebral pain centers. The pathogenesis of stump pain is complex involving psychologic as well as organic factors.

Faultless surgical technique in amputation is a prerequisite for prophylaxis of stump pain. Neuroma can best be avoided by ligation with nonresorbable suture followed by alcohol injection or better still by injection of 2 per cent gentian violet. Once the stump has healed one has to consider re-education of the amputee, occupational rehabilitation, restoration of morale and social readjustment.

Innumerable analgesic drugs have been tried in the effort to relieve stump pain. Morphine should be avoided. The administration of vitamin B₁ in daily doses of 10 cgm by intramuscular injection is strongly recommended. Roentgen therapy may be applied to the stump, adrenal region or cervicodorsal region. Alcohol injections into nerve trunks are to be avoided, but local injections of novocain about a neuroma may prove beneficial. Psychotherapy may be indicated.

Surgical operations for relief of stump pain are directed toward removal of some lesion believed responsible for the pain stimuli. Interruption of the paths of pain conduction changing the mechanism of pain perception by cerebral operations or finally toward achieving a sedative effect by surgery on the sympathetic system. Indications for various procedures

dures must be strictly individualized and it is a grave mistake to try various procedures in succession. Recurrence of pain following temporary relief is not uncommon. It may be necessary to operate on the bone in cases of infection or on the vessels in cases of arterial or arteriovenous aneurysm. Associated osteoarticular lesions may require reamputation. Resection of neuroma should be reserved for very special cases. Reamputation usually yields poor results. Filatov and Kraus have suggested subcutaneous inclusion of tiny flaps of skin or fragments of specially prepared amnion.

Operations devised to interrupt pain conduction include division of the nerve trunks, radicotomy, posterior commissural myelotomy, anterolateral cordotomy and mesencephalic tractotomy. None of these yield constant results and many are associated with serious complications. Even complete anesthesia of the stump will not necessarily render it painless. Brain surgery for the relief of stump pain includes cortical resections and prefrontal leucotomy. These need further testing.

Periarterial sympathectomy yields only transitory results and has been abandoned in favor of infiltrations or more extensive resections. When these are contraindicated periarterial sympathectomy may be tried. Arterectomy may afford relief in cases of arterial obliteration and a routine inspection of the arteries is indicated in all amputation cases. Para-vertebral infiltrations and intra-arterial injections are valuable adjuncts. Infiltrations are used preliminary to chain resections and serve as a guide as to what results may be expected. They have also therapeutic value per se and can be repeated if necessary. Infiltration often suffices in early cases, but not in cases of long standing or following repeated operation. The indications for intra-arterial injections, chain resections, and stellectomy are enumerated with special indications for upper and lower limbs.

Sympathectomy is the method of choice for relief of stump pain and may sometimes effect a cure.

It is especially successful in diffuse stump pain, especially if associated with vasomotor or trophic disturbances. Even pain referred to a phantom stump may respond to this treatment. The sedative effect is not always apparent at first but develops progressively. Sympathectomy will not relieve all cases however and is not recommended as a routine method. In early selected cases it may afford marked and lasting relief. Contraindications include organic taint, drug addiction and repeated previous futile operations as well as mental disease.

Reamputation is not recommended for relief of pain but only for special indications. In neuroma roentgen therapy may be tried before operation. Anastomosis of the adjoining nerves has yielded very few good results.

One is justified in trying intra-arterial injections of novocain or chain infiltration even though sympathetic symptoms be lacking. If these fail radiculo-medullary intervention is indicated cordotomy being preferable for the lower limb. Periarterial sympathectomy is a simple operation. It can be done under local anesthesia and is more elective as regards sparing visceral innervation. In leg involvement it is best to resect the sympathetic chain and especially the second lumbar ganglion. In arm involvement one may have to choose between classic stellectomy, section of the rami of the vertebral nerve and isolated resection of the second and third thoracic ganglions, or such resection associated with stellectomy. Opinions vary as to the respective value of these methods. Resections in the cortical zone and prefrontal leucotomies are still in the experimental stage. In hyperalgesic patients it may be useful to try roentgen therapy, ionization and psychotherapy including isolation and electric shock therapy. In desperate cases, in which the patient may be driven almost to suicide by the failure of all tried methods, it would seem justifiable to try some of the recent brain operations.

EDITH SCHAMBERG MOORE.

peripheral blood vessels must be watched very carefully with thorough inspection and palpation of the affected extremity at short intervals throughout the first 24 or 48 hours after the injury. Vasodilating substances should be given regularly for the first 2 days and oral administration of alcoholic beverages is a very satisfactory way of producing peripheral vasodilatation. The complete novocainization of the regional sympathetic ganglia will also provide maximum peripheral vasodilatation and should be done every 10 to 12 hours during the first 48 hours after the injury to obtain maximum clinical benefits. It is extremely important to keep the extremity at the proper resting level. An ischemic extremity should be kept at a position about 6 or 8 inches below the level of the heart in order to provide the maximum exchange of blood in that extremity. If it becomes mottled or cyanotic, elevation above the level of the heart for one to two minutes may be advisable and gentle stroking of the skin from the distal parts of the extremity proximally will frequently free the superficial capillaries of the static blood. The use of heparin and dicumolol now makes it possible to reconstruct large arteries without having the results nullified by secondary thrombosis. If the coagulability of the blood is reduced by these substances for a period of 10 days or 2 weeks, healing of the injured or repaired artery or vein takes place and no further intravascular blood clots will form at that point.

HERBERT F. THURSTON, M.D.

The Borrowing-Lending, Hemodynamic Phenomenon (Hemometakinesis) and Its Therapeutic Application in Peripheral Vascular Disturbances. MICHAEL E. DEBAKEY, GEORGE BURCK, THOMAS RAY, and ALTON OCHSNER. *Ann Surg* 94:7 26-35.

The authors note that it is now a well established fact that the volume of organs undergoes spontaneous, and even rhythmic, variations, primarily attributable to changes in the volume of the blood within the particular part. When more refined techniques of plethysmography were developed, it became practical to carry out accurate quantitative studies of the fluctuations in volume in such peripheral parts as the pinnae, the fingers and the toes and thus to secure much valuable information under normal resting conditions as well as in diseased states. Certain facts have been established which not only have a fundamental physiologic significance but which also appear to have a definite bearing upon certain clinical conditions.

It is the purpose of this communication to consider these facts as the basis of a concept which the authors have chosen to call the "borrowing-lending" phenomenon and for which they suggest the term hemometakinesis. A discussion of plethysmography is presented.

It is noted that the plethysmograms of normal individuals under certain circumstances present variations of considerable degree which may resemble the changes found in diseased states. Of particular

importance among the factors which may produce such changes are (1) the psychic state of the individual, (2) the environmental temperature, (3) the relation of the part to the heart level, and (4) interruption of the sympathetic pathways to the part. Numerous observations made upon normal individuals as well as on patients with various forms of peripheral vascular disease have invariably been consistent, regardless of the methods employed to determine and record variation in blood flow. Special studies have been made by thermometric and plethysmographic methods. Observations made upon 2 patients are presented in detail.

In conclusion the authors note that although gaps still exist in our knowledge of the hemodynamics of the peripheral circulation under normal resting conditions and disease states, the evidence at hand justifies certain statements that there is a continuous shifting back and forth of blood from one part of the body to another for this "borrowing-lending" mechanism the term hemometakinesis is proposed that hemometakinesis seems to indicate the existence of a well regulated mechanism which permits the body to utilize its limited total blood volume in the most efficient manner to meet variations in local requirements, and that the essence of this mechanism seems to lie in the control and regulation of the vascular bed which permits an increase in the volume of blood of one part of the body with a corresponding simultaneous decrease in the volume of blood in another part without any alteration in the total blood volume.

It is suggested that these principles of hemodynamics are applicable to the management of peripheral vascular disease, the effective therapy of which is based on improvement in the circulation or an increase in the blood supply of the part. Measures directed toward the improvement of the local circulation by production of dilatation of the entire vascular bed are of doubtful value whereas measures directed toward local vasodilatation are in conformity with the natural "borrowing-lending" mechanism (hemometakinesis).

The most effective method of increasing the local blood supply is sympathetic denervation of the affected part. In addition, it is in complete conformity with the concept of hemometakinesis.

Two cases, selected from a large experience, are presented to illustrate the concept of hemometakinesis and to demonstrate the value of sympathetic denervation as a therapeutic measure in peripheral vascular disease.

HERBERT F. THURSTON, M.D.

Aneurysm of the Pulmonary Artery: Review of the Literature and Report of a Case. RALPH A. DETERLINO, JR., and O. THORSON CLAGETT. *Am Heart J* 94:7 34-47.

The authors present an analysis of 36 cases of aneurysm of the pulmonary artery (proved at autopsy) collected from the literature. The addition of this group to the 111 cases proved at autopsy and reported by Boyd and McGavack in 1939 brings the

total number of authentic cases to 147. The facts that the incidence according to sex is the same and that the patients concerned are relatively younger help to distinguish this type of aneurysm from that of the thoracic aorta. Although syphilis was a definite factor in more than a third of the cases, congenital cardiovascular anomalies also play a major role. A patent ductus arteriosus is present in more than 30 per cent of cases. Other less common causes are subacute bacterial endocarditis, atheroma, and trauma.

The early symptoms are dyspnea, cough, and pain in the thorax. Cyanosis and edema usually are later manifestations often dependent on cardiac failure or congenital anomalies. The heart, especially the right ventricle, frequently is enlarged. Right axis deviation is common in the electrocardiogram. Most significant is the roentgenologic and roentgenoscopic finding of a discrete pulsatile hilar mass separate from the aortic shadow. Usually no special means of examination is necessary as a supplement to roentgenoscopy.

A detailed report of a case is presented. The condition of the patient was interesting in that the clinical diagnosis was confirmed by necropsy. There were a patent ductus arteriosus, atheroma of the right pulmonary artery and bilateral pulmonary arteriosclerosis, as well as a history of trauma. Surgical cure by ligation of the right pulmonary artery and pneumonectomy was prevented by the extent of the aneurysm and the atheromatous calcification of the vessel concerned.

Experimental Reproduction of Arteriovenous Fistulas (Sulla riproduzione sperimentale delle fistole artero-venose) LUIGI GIZZETTI *Chirurgia*, 1947

Large healthy young dogs were used in this study and the arteriovenous fistula was established between the femoral vessels in 8 and between the common carotid artery and the external jugular vein in 4. Vascular suture was performed with very fine needles and vaselined black silk. Temporary hemostasis of the vessels operated upon was obtained with clips sheathed in rubber and regulated by a screw

which allowed the application of even pressure on the entire vascular wall and after removal a slow gradual return of the circulation. Laterolateral anastomosis was performed in every case. For example, a longitudinal incision was on the femoral vessels, a longitudinal incision of from 12 to 15 cm. was made over the root of the thigh and the artery and vein were isolated for 6 or 7 cm. the clips were then applied proximally and distally on each vessel and small scissors were used to remove from the arterial and venous walls an oval portion from 5 to 6 mm. long and from 3 to 3 mm. wide. The lips of these eyelets were united with a continuous suture, after which reinforcing suture points were placed where necessary and the clips were gradually removed first from the vein and then from the artery.

This technique was changed in some of the animals by ligating the artery below the anastomosis so as to compel the blood to run through the vein peripherally and centrally by ligating the artery and the vein below the anastomosis to compel the blood to run through the vein centrally or by ligating the artery below and the vein above to compel the blood to run through the vein peripherally only.

All animals recovered and the fistulas remained patent which allowed the author to study the local and general changes in the circulation, the behavior of the arterial and venous pressures, and the histologic structure of the anastomosed vessels. His findings show that the creation of a permanent communication between artery and vein first causes a fall in the arterial pressure and a rise in the venous pressure, which become less marked and finally reach normal values with the lapse of time. The structural changes in the anastomosed vessels are unimportant and no real arteriovenous aneurysm has ever been produced, because of the high sclerosing capacity of injured tissues in the dog.

In addition, the serious cardiac complications described in man have not occurred in the dog. This depends evidently on the difference between the adaptability of man and the experimental animal to the artificial circulatory disturbance and on the possibility that the powers of cardiac compensation are greater in the dog.

RICHARD KEMEL, M.D.

SURGICAL TECHNIQUE

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

The Definitive Program for Embolus Prophylaxis at the Freiburg Surgical Clinic and Its Results (U ber die abschliessend Durchfuehrung der Embolie-Prophylaxe an der Freiburger Chirurgischen Klinik und ihre Ergebnisse) E. KERN *Dtsch med. Wochschr.* 1947 73 595

In his previous publication the author described the procedure followed at the Freiburg Clinic to achieve embolus-free surgery without the danger of postoperative hemorrhage. Because of the scarcity of anticoagulant material at that time the procedure could not be employed for all of the patients at the Clinic. The present report deals with the expansion of the program and the extension of the procedure throughout the entire Clinic.

The program is based on the fundamental role played by prothrombin in the clotting process and in thrombosis. It involves methods for the recognition of impending thrombosis and a consideration of the kind and dosage of anticoagulant substances to be used. Clinically it is important to prevent massive and propagating thrombosis in order to eliminate embolism. Physiological and locally circumscribed thrombosis, as well as locally circumscribed thrombophlebitis are beyond consideration in this study since they do not lead to embolism or other late complications. A distinction is made between a thrombotic tendency and the actual danger of thrombosis.

Further extension of the procedure has confirmed the previous opinion concerning the definition and recognition of the danger of thrombosis, but there has been some revision of the concepts with respect to a thrombotic tendency. Certain conditions giving rise to a thrombotic tendency do not always result in thrombosis but when an excessive amount of prothrombin is released into the blood stream under these conditions, danger of thrombosis ensues. Thus, the central factor is the prothrombin level which in turn depends upon numerous disturbances leading to a sympathetic dystonia. The author now considers the problem from the standpoint of a constitutional or an acquired sympathetic nervous system lability which leads to thrombosis and embolism. Evidence to support this view is presented.

For 3 years dicumarol has been used exclusively in the Clinic as the anticoagulant substance. The control test depends upon the determination of the prothrombin index and the clotting time. Since the author's prophylactic method has been employed throughout the entire Clinic, complete success has resulted inasmuch as embolism has not occurred in any case subjected to control testing and management.

JOHN L. LUDGOWITZ M.D.

Chemotherapy in Gas Gangrene: An Experimental Study W. A. ALTMEYER, W. L. FORTER, and W. E. COLLEMAN. *Arch. Surg.* 1947 55: 668.

Because of conflicting evidence obtained from numerous clinical and experimental reports concerning the use of chemotherapy in gas gangrene, the authors have made an experimental evaluation of the use of penicillin and streptomycin in gas gangrene.

In all of the animal experiments previously carried out on guinea pigs, the infections were produced by inoculation of bacterial cultures through hypodermic injection into healthy tissues, and in some instances an irritant was used. Infections produced under such conditions were different from those seen clinically in which devitalized and degenerated tissues are prominent characteristics. In the authors' opinion, this difference was largely responsible for the discrepancy obtained between the effectiveness of penicillin in gas gangrene experimentally produced and its questionable value in the type occurring clinically. A method was therefore devised of measuring accurately the value and limitations of chemotherapy in standardized experimental gas gangrene which was produced in the presence of crushed muscle and dirt and which simulates closely the conditions seen clinically.

A virulent strain of clostridium welchii was used. The penicillin used was the commercial salt presently available, and the streptomycin used was in the hydrochloric form. The infection in the guinea pigs was produced by the inoculation of measured quantities of bacteria in closed wounds containing crushed muscle and sterilized dirt, using a uniform procedure in each animal.

The authors found that the experimental infection produced in the presence of crushed muscle and dirt was considerably different from that produced by the simple injection of bacteria with or without local irritants into healthy muscle. It was not only much more severe but also much more refractive to therapy. In the severer form of gas gangrene in animals, penicillin was proved to be the chemotherapeutic agent of choice, while streptomycin was found to be of little value. It was also found that penicillin was much more effective when used prophylactically than when used in infections already established. This emphasized the advisability of starting parenteral administration of penicillin as soon after injury as possible and before debridement. The longer chemotherapy was delayed, the more limited the response was found to be.

It was also significant that under the challenge of severe infection penicillin had little or no measurable value when used either prophylactically or therapeutically in the average dose. However when the dose was increased sixteen times its effect was prophylactically obvious and only when it was increased

forty-eight times did its therapeutic effect become unquestionable. This undoubtedly explains many of the differences in the clinical results obtained with penicillin.

The authors have purposely placed penicillin to its most severe test in their experiments. The tained crushed muscle and dirt and also were closed with sutures and were not treated subsequently by any surgical incision or excision. In this factor was eliminated. However it is still the authors opinion that early and adequate surgical treatment should be considered the most important factor in the prevention of clinical gas gangrene and that parenterally administered penicillin can be expected to be a valuable therapeutic adjunct.

In these studies penicillin checked the invasive qualities of the infection both retarding its development and limiting its spread under adverse conditions. This fact suggested that early clinical use of penicillin in large doses up to 1,000,000 units every 3 hours would probably have the following effects: (1) limitation of the invasive qualities of the infection and prolongation of the period during which effective surgical procedures short of amputation can be done (2) the possibility of amputation at lower levels resulting in less mutilating sequelae when amputation is necessary in advanced infections (3) inhibition not only of the secondary bacterial invaders usually susceptible to penicillin but also of many of the organisms ordinarily resistant to the average doses of penicillin and (4) marked reduction in the mortality.

JENN E. KARANIN M.D.

Amebic Abscess of the Left Buttock. T. C. MORTON and S. F. SOUTAR. *Brit. M.J.* 1947 2 906.

Cutaneous amebiasis may be grouped in one of five classes: (1) secondary in incision and drainage of amebic abscess of the liver, (2) secondary in drainage of an amebic appendiceal abscess (3) following colostomy for amebic colitis (4) in association with anal disease of amebic origin, or (5) primary cutaneous amebiasis.

Criteria for the diagnosis of amebiasis cutis are based on histological proof of amebic invasion of the skin the demonstration of ameba by smear and the culture in the skin ulcer and therapeutic response to emetine or other antiamebic drugs.

Included in this article is the report of a case of amebic ulcer of the buttock in a symptomless cyst carrier. The lesion first appeared as a simple buttock abscess. The etiology of this abscess may be accounted for on the basis of secondary amebic infection in a discharging staphylococcal abscess although it is not improbable that *E. histolytica* infection of the rectum could have spread primarily through the lymphatics into the ischio-rectal space. This condition should be considered in the treatment of former military personnel who served in the tropics.

ANESTHESIA

The Effect of Carbon Dioxide Inhalation in the Prophylaxis of Postoperative Respiratory Complications. G. E. H. ENDERBY. *Anaesthesia*, 1947 2 12.

In a survey of cases of bone graft operation the author found that carbon dioxide inhalations greatly reduced the incidence of postoperative respiratory complications. A very important feature of all these operations has been the site from which the bone was obtained. This involved the iliac bone and caused a great disturbance of the normal muscular activity employed in respiration, particularly in coughing. Carbon dioxide (5 per cent in oxygen) was given with a catheter or the B.L.B. mask for 15 minutes hourly on the day of operation and during the first postoperative day. During the second day inhalation was carried out for 10 minutes every third hour and during the third day for 15 minutes 3 times during the day. Recently a closed system of carbon dioxide and air using the patient's own carbon dioxide has been tried and has been more satisfactory in stimulating coughing.

MARY FRANCES PINK, M.D.

Anaesthesia in the Surgical Treatment of Bronchiectasis. L. H. MOUSSEL. *Proc. R. Soc. M. Lond.*, 1948, 238 148.

Care of patients who are to be treated surgically for bronchiectasis needs to be planned in a logical manner if anaesthesia mortality and postoperative complications are to be held to a minimum.

The problem is considerably simplified with the use of penicillin nebulization in the preoperative preparation. The Trendelenburg position is not employed because of the increased danger of filling the upper lobe bronchus of the dependent lung with foreign material. Controlled respiration is never used because of the hazard of gravitating foreign material and causing an unrecognized obstruction in one or more of the lobes of the dependent lung.

After pentothal induction in the patient a room nitrous oxide and oxygen and then ether are given in carry the patient to light third stage first plane anaesthesia. The trachea is intubated with a short Magill endotracheal catheter carrying an inflatable cuff. When ether and oxygen anaesthesia is being used hilar infiltration is not necessary to lessen the danger of severe reflex activity during manipulation.

The lung is decompressed slowly to prevent mediastinal flutter and paradoxical respiration. If diaphragmatic movements are observed at all times, tracheobronchial obstruction or mediastinal flutter can be detected several minutes before positive clinical signs are apparent in the character of the blood pressure and pulse and before cyanosis develops.

All anaesthetists should be able to pass a bronchoscope with the patient in a lateral position so that direct visual aspiration of the tracheobronchial tree can be carried out if necessary. If for any reason the patient develops cyanosis or has a severe change in the pulse or blood pressure the bronchoscope is re-

moved immediately. Death may be due to asphyxiation because the tip of the bronchoscope has been wedged into a lower bronchus for a prolonged period, completely obstructing the patient. After bronchoscopy x-ray examination of the chest is performed while the patient is still on the operating table. Bronchoscopy is repeated if indicated before the patient is returned to his room. Once the slightest amount of postoperative atelectasis or tracheobronchial obstruction develops bronchoscopic aspiration is done.

MARY FRANCES POE, M.D.

Spinal Analgesia and Cauda Equina Lesions. TOM DIXSON, *Lancet* 1947 7

Nervous complications in the form of cauda equina lesions have occasionally followed spinal analgesia. Twenty-one reported cases and the present views on causation are reviewed. All the recorded evidence condemns the use of concentrated solutions which are kept in contact with the sacral roots for a long period.

As a result of his investigations, the author became convinced that a spinal solution should be as dilute as is consistent with efficacy and isotonic with cerebrospinal fluid. The following formula was produced: amethocaine 0.02 gm (0.4%) dextrose 0.23 gm (4.6%) water 5.0 c.c. (specific gravity 1.018 pH 5.0). There is evidence that amethocaine is one of the safest analgesic agents known. This solution is above the minimal effective subarachnoid concentration, while being more dilute than any other heavy spinal solution so far used. It is isotonic and requires no dilution with spinal fluid. A table shows the dosage used.

Although this solution has been used for over a year without neurological sequelae, no conclusions can be drawn until the total administrations reach a large figure.

MARY FRANCES POE, M.D.

Continuous Caudal Analgesia in Obstetrics, Surgery and Therapeutics. ROBERT A. HILSON, *Current Res. Anesth.* 1947 26 77

A survey of the history of continuous caudal analgesia indicates that many physicians from all parts of the world have added step by step to the existing knowledge of its clinical application.

Since 1915 a total of 165 scientific papers have been published with reports of the labors and deliveries of more than 200,000 patients and numerous surgical operations managed by this technique.

Forty-three maternal deaths have been reported. Of these 11 occurred during the period of analgesia and unquestionably were related to this method of administration. Death of all 11 patients was considered preventable.

The pains occurring in the terminal portion of the first stage of labor and the second and third stages of labor and the postdelivery pains are controlled completely in more than 90 per cent of the cases. In 5 per cent of the cases there was failure to obtain relief because of anatomic or technical difficulties. The method was designed to relieve intolerable pain and not the discomforts of early labor. The technique

completely alters the process of labor as it has been described in our present-day texts. It has doubled the incidence of operative deliveries in occipitoposterior presentations, transverse arrests, and outlet forceps extractions. Its influence on the blood pressure of mothers is one of the most serious hazards associated with the technique. The quantity of blood lost in delivery and in the third stage of labor (60 to 200 c.c.) is uniformly diminished. Coagulability of the mother is not impaired, the involution of the uterus is expedited, and it maintains its response to neurogenic and oxytocic stimuli.

In the author's experience no permanent residual complications attributable to the method have occurred. The incidence of initial postpartum catheterizations was slightly increased in cases managed by this method. The results obtained in 2,500 consecutive deliveries under continuous caudal analgesia were compared with those obtained in 1,000 controlled deliveries and 3.6 per cent of the total number of infants delivered under caudal analgesia did not breathe for a period of 5 minutes or longer after birth as compared with 0.6 per cent of the total number of infants in the controlled group. Two and one-half per cent of the infants delivered with the aid of caudal analgesia required the use of a special pharmacologic agent to induce respiration as compared with 3.7 per cent in the controlled group. One hundred and seven premature infants were discharged alive from the hospital in the group managed under caudal analgesia as compared with 330 premature infants in the controlled group. Stillbirths amounted to 0.9 per 1,000 live births in the group managed under caudal analgesia as compared with 24.8 per 1,000 in the controlled group. Deaths in the first week of life in the group managed under caudal analgesia amounted to 11.5 per 1,000 live births as compared with 20.8 in the controlled group.

Taking into account both stillbirths and neonatal deaths the total loss of infants amounted to 20.6 per cent per 1,000 live births in the group delivered under caudal analgesia as compared with 45.6 per cent for the controlled group. The neonatal mortality in the group managed under caudal analgesia was 169 per 1,000 live births as compared with 294 in the controlled group.

MARY FRANCES POE, M.D.

Continuous Caudal Analgesia in Obstetrics, Surgery and Therapeutics (Conclusions). ROBERT A. HILSON, *Current Res. Anesth.* 1947 26 138

Estimates based on the study of deliveries in the Philadelphia area, and expanded to include conjecturally the entire country, indicate that the newer methods of delivery would cut in half the present loss in infants through stillbirth and death under one week old. More specifically of the total of 123,000 viable infants lost by stillbirth or death within the first week of life it is estimated that the loss of 67,000 infants, more than one half could have been prevented by the use of newer methods.

Epidural anesthesia through the technique of continuous caudal analgesia has been instituted as a

variable adjunct in the following conditions (1) diagnosis prognosis and therapeutics of essential hypertension (2) treatment and control of the toxemia of pregnancy and eclampsia and convulsions (3) treatment of patients with uremic convulsions and prolonged anuria developed during sulfamides therapy for pneumonia (4) diagnosis and therapeutics of peripheral vascular disease

The changes which develop in the body with continuous caudal analgesia involving the eighth thoracic segment are skin analgesia to pain and thermal stimuli cessation of sweat in that area increase in surface temperature in this area of from 8 to 20 degrees, increase in the capacity of the vascular bed of the lower trunk by 500 to 800 cm of blood relaxation of the rectal sphincter and the perineal musculature, temporary hypotension hyperperistalsis of the intestinal tract, conduction nerve block of pain impulses from the uterus bladder and adnexa, and gradual relaxation and development of motor anesthesia of the muscles of the lower trunk and extremities

MARY KARP M.D.

Pharmacologic and Clinical Study of a New Oxytocic Analgesic Combination (Etude pharmacologique et clinique d'une nouvelle association oxytocique-analgésique) E. LEVI SOLAL, F. MEYER, and A. REMUEUR. *Industrie et Par* 1946-47 61

After many clinical and pharmacodynamic tests in their effort to find an ideal oxytocic-analgesic combination to achieve attenuated labor pains rather than 'painless labor' the authors adopted the following formula 206 R.M.

Phenylpropionate of dihydroxypropylacetate 5 ampoules (0.005 gr)
Camphorsulfonate of dihydroxypropylacetate 7 ampoules (0.007 gr)
Camphorsulfonate of scopoline 5 ampoules (0.005 gr)
Spartine sulfate of epinephrine 5 ampoules (0.05 gr)
Physiologic sodium chloride solution to fill ampoules of c.c.

This formula is administered in a dose of 4 c.c. or 2 ampoules in a first injection, and an additional dose of 2 c.c. or 1 ampoule should be injected later if it is required. Because of its ingredients, this formula exerts a normalizing effect on the respiration a vagolytic and neurosedative effect, a balancing effect on the sympathetic nervous system an anti-toxic and antishock effect, as well as a cardiotonic isolated uterus of various animals is described. Sparteine exerts a stimulating effect on the contractions and tonus of the isolated uterus. The rate and increased even with small doses. With the formula 206 R.M. the changes in tonus are negligible, where as the amplitude of the contractions is considerably increased.

Clinically the patient is instructed that the labor will not be completely painless, and that for 15 minutes after the injection. In primiparas the injection is made as soon as the head is definitely engaged and before the stage of excitement and

severe pain. The patient is instructed to remain as quiet as possible in dorsal decubitus, breathing deeply and regularly. In multiparas the injection is made at the beginning of labor with the cervix obliterated and the head fixed in a well formed inflexion segment. Four cubic centimeters or 2 ampoules of the solution are injected intramuscularly. Should a second injection be required one half of the initial dose is employed accompanied by an injection of coramine. A second injection should never be made at the stage of full dilatation. A slight mydriasis may require shielding from direct light and thirst due to partial inhibition of salivation can be allayed by a few draughts of water. In excited, hypersensitive women a second injection as described may be made about 15 minutes after the first injection should the latter have no analgesic effect. There are no maternal contraindications to this method the heart disease, tuberculosis or albuminuria. Only uterine hypertension during labor may sometimes prove an obstacle to its use.

Statistics are presented on a series of 110 cases from the Maternity Hospital at Baudeloque. The position of the fetus was not a determining factor. Of the 110 deliveries 94 were natural and 16 were made with forceps probably because the patients had excessive pain difficult presentations or other complications. In 4 of the latter cases errors in judgment had been made such as repeated injections of totopon and spasmalgin without the simultaneous injection of an oxytocic dose of sparteine or late. There was no adverse effect on the mother or infant mortality was zero. If general narcosis or chloroform have been used, reinjection must be accompanied by the simultaneous administration of coramine. The general effect on the mother is excellent. Contraction pain is greatly diminished and the analgesic effect lasts from 3 to 5 hours as a rule occasionally only 1 hour and sometimes 6 or even 10 hours.

Very good results were reported in 47 patients (39 receiving 1 injection and 8 a second injection) and good results in 39 patients (36 receiving 1 injection and 3 a second injection). In 5 cases contractions were present but it was less severe than before the injection. The method failed in 7 cases or 6.5 per cent. Fifty-eight deliveries were painless to slightly painful, 26 painful, and 16 patients had to be delivered under a general anesthetic with forceps. Thus, in all a very good result could be claimed in 78 per cent of the cases.

EDITH SCHIANTER MOORE.

Intravenous Anesthesia
(Anesthesiology 1947 8 489)

R. CHARLES ADAMS, Anest.

Much has been heard during the last few years about the way intravenous anesthesia is displacing other methods. It appears that it is complementing other methods rather than displacing them. Most of

the difficulties that have arisen in connection with intravenous anesthesia have resulted from attempts to make it do the work that other methods could do as well or better. On the other hand there are count less instances in which intravenous anesthesia can be used to obviate some of the undesirable features of other methods resulting in better anesthesia than could be obtained otherwise.

Dilute solutions of alcohol employed intravenously constitute a useful postoperative analgesic and sedative agent, particularly in the aged. Dilute local anesthetic solutions administered by slow infusion are now successfully used to relieve cutaneous itching as in jaundice or to alleviate certain types of pain. Procaine hydrochloride used intravenously is said to be of value in controlling cardiac arrhythmias under general anesthesia.

One thing is certain intravenous anesthesia will not regress. Patients like intravenous anesthesia—whether it is good for them or not. This preference has been a important factor in the trend toward intravenous anesthesia as a method of induction of anesthesia if for nothing else.

There is not much that is new in the field of intravenous anesthesia at present only a new and better agent can change it. The principles underlying the intravenous use of a general anesthetic agent are sound. If we can by-pass the respiratory tree by injecting the anesthetic agent directly into the blood stream, we can circumvent some of the difficulties associated with inhalation anesthesia. The factors that may prevent an agent from reaching the pulmonary circulation may not be the same problems when the intravenous route is employed. In intravenous anesthesia there is less tendency toward the production of mucus since irritation of the mucous membrane is less. Nausea and vomiting which result in part from the swallowing of the anesthetic agent are definitely decreased.

The administration of ether by vein may still have merit in certain types of cases. Many of the technical disadvantages of earlier years have been obviated by modern equipment and methods of infusion. Certain drawbacks persist. The concentration that can be used is limited by the rate of infusion and the total volume of the vehicle.

The alternative is the use of some supplementary agent. Cyclopropane has been the best gas for this purpose when it is employed small amounts of ether will provide excellent relaxation. Pentothal sodium also is satisfactory. The depressing effects of large doses of pentothal sodium are avoided and some of the undesirable sequelae that follow ether administered by inhalation are minimized. Pentothal sodium can be used with any of the gases or ether and is outstanding as a supplement to local regional and spinal anesthesia. One of the most important uses of pentothal sodium has been to provide anesthetic combinations which are thoroughly free from the hazards of fire and explosion and which permit the use of all types of electrosurgical instruments. Large doses of pentothal sodium are potentially hazardous

even though the patient may not appear to react untowardly. Anoxia as a result of respiratory depression may not always be apparent in the patient's general appearance.

Since pentothal sodium falls short of producing total anesthesia with safety it is necessary to continue to think in terms of compensating for this deficiency. The results obtained to date with pentothal sodium and curare have been promising, and the reduction in the amount of pentothal sodium permitted by such a combination has been marked. The combination certainly is not so dangerous as was formerly supposed. The author hesitates to say whether or not this combination will provide a safe method of anesthesia for abdominal operations. Both agents are potent respiratory depressants and, as such must be administered with due caution. Endotracheal intubation carried out with the patient under the influence of pentothal sodium has never been very satisfactory. The addition of curare has greatly increased the ease of introduction of the tube. One other advantage of use of the combination is the resulting lessened incidence of laryngospasm which is often so troublesome when pentothal sodium is used alone. The combination of curare and pentothal sodium was used by the author in a few cases of poliomyelitis to alleviate spasm. The use of pentothal sodium with curare made application of the treatment and the treatment itself easier for the patient to tolerate. The supervised use of pentothal sodium by persons other than physician anesthesiologists cannot be condoned.

The most important thing in the teaching of intravenous anesthesia is recognition of the inherent limitations of the method and that it accomplishes certain things that are eminently desirable in a method of anesthesia.

The Influence of the Constitution of Acids Combined with Alkaloids, Local Anesthetics, and Sedatives on the Pharmacodynamic Activity of Salts. Studies Pursued during the Past 5 Years. Present Status of the Question (Influence of la constitution des acides combinés ou alcaloïdes, anesthésiques locaux et sédatifs, sur l'activité pharmacodynamique des sels. Travaux effectués pendant ces cinq dernières années. Aspect actuel de la question) JEAN RÉORTER. *Analgesia* Par 1946-47 6-25.

The author is convinced that the theory that the pharmacodynamic effect of an alkaloid salt depends exclusively upon its basic alkaloid portion is erroneous. The role played by the acid portion has been demonstrated as important not only in cocaine morphine and emetine but also in a substance which might be designated as para-alkaloid the base of novocain: para-aminobenzoylethylaminocetanol. The basic alkaloid portion is truly responsible for the pharmacodynamic effect, but the acid with which the alkaloid is combined intervenes to increase or diminish the primary effect, both as regards intensity and duration. The effect of the salifying acid on the activity of the base has been demonstrated not

only for complex organic but also for inorganic bases such as ammoniac and alkaline bases. Here the basic portion is quite simply opposite to the acid portion, the influence of which eventually predominates, and thus we find one ammoniac salt not nutritive to *Aspergillus* while another is, and one salt of potassium inducing sporulation of *Bacillus perfringens* while another potassium salt fails in this respect.

Such phenomena may be attributed to the fact that the saline molecule differs from the basic molecule. The role of polar groupings in these phenomena is emphasized. Organic salts may be divided into those formed by acids with polar groupings and those formed by acids without polar groupings. Sometimes the former are indicated (local anesthesia of the mucosae, rapid sedative effect, toxic effect in vitro on *Protista*, action favoring sporulation) and sometimes the latter (slow sedative effect, nutritive action on molds). However that may be the influence of the presence or absence of polar groupings in the salifying acid is clearly apparent in the effect. Practical applications of these findings are suggested.

In 1912, the author demonstrated that the diethyl acetate of the base of novocain had essentially the same anesthetic properties as the isobutyrate and the phenylpropionate of the same base, but was minus the unpleasant odor which has interfered with medicinal use of these salts. Corrected of a rather excessive vasodilating property this new salt has yielded interesting results as an ocular anesthetic. In the same year it was shown that the phenylpropionic amide of the novocain base had 65 times as great an effect on the cornea as the hydrochlorate of para-aminobenzoyldiethylaminoethanol (novocain) the toxicity being 2.4 times less than that of novocain.

Unfortunately clinical tests showed that the new substance could not withstand sterilization or storage and that freshly prepared solutions with strong anesthetic power formed a precipitate with albuminous exudates, which were deposited on the mucosae or formed a small pellicle obscuring the anesthetized surface.

These clinical experiments do show however the possibilities of phenylpropionic amide as a base or hydrochlorate to replace cocaine in Bonain's mixture.
EDITH SCHAMCHER MOORE.

SURGICAL INSTRUMENTS AND APPARATUS

The Chondrojet. E. HOTT DEHLIZKE. *Plast Reconstr Surg* 1948 3 95.

The author describes a new instrument and technique which facilitates the handling of diced cartilage for reconstruction of contour defects of the face. Diced cartilage implies material chopped into 1 to 3 mm multifaceted particles. Customary methods of burying this material require rather large incisions directly over the defect. This has cosmetic disadvantages as well as increasing the likelihood of extrusion of cartilage fragments, bacterial contamination, and increased operating time.

The chondrojet consists of a straight steel tube with a syringe type piston and finger grips, and a funnel and tamper for loading. Incisions are made a few centimeters from the recipient area. In conspicuous places a tunnel is then dissected to the recipient site the loaded chondrojet is introduced through this tunnel and its contents are extruded. After closing the incision the cartilage mass is molded in a smooth contour and pressure dressings are applied.

This method was carried out 17 times on 11 patients with gratifying results. The operating time was reduced over 50 per cent, no major infections were encountered, loss of cartilage fragments by extrusion was negligible, and scars were inconspicuous. Serum accumulations were frequent and were treated by aspiration. Locations and conditions included receding chins, malar and frontal depressions, depressed orbital floors and asymmetrical mandibles. Local anesthesia was used and in all cases preserved rib cartilage implants were employed. It is the author's opinion that living cartilage grafts offer no advantages over preserved cartilage implants.

S. LLOYD TRITTMAN, M.D.

PHYSICO-CHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Critical Evaluation of the Tomographic Method in Laryngeal Carcinoma (*Valutazione critica del metodo tomografico del carcinoma laringeo*) PIRELLI C. *Chir. Radiol. Med.* Milano 1947 33 5 5

This evaluation is the result of an analysis of more than 60 patients who were subjected to total laryngectomies after thorough clinical laryngoscopic roentgen and tomographic studies. The specimens were used before fixation to compare the anatomic and roentgen findings. In all cases the roentgen examination included a normal teleroentgenogram of the larynx in lateral exposure and a series of 4 tomograms in frontal exposure. Only in case of special need were tomograms taken also in lateral exposure.

The first tomographic plane is located about 1.5 cm. from the anterior plane and its axes intersect the anterior extremity of the anterior cartilaginous commissure and the body of the hyoid when the larynx and neck are of normal thickness. The other planes are 0.5 cm. apart and intersect successively the laryngeal ventricles in their middle and posterior third and the arytenoids. Also depending on its position the free part of the epiglottis is shown in the second third or fourth plane. When in addition to the regular lateral roentgenogram it is necessary to obtain tomograms in sagittal exposure as for instance in the presence of a thyroid cartilage that is markedly calcified or ossified and masks the shadow of the laryngeal soft tissues four tomograms are taken—two on each side at 3 and 8 mm. from the median line respectively. In the normal larynx the internal planes will fall on the vocal cords and the arytenoids and the external planes will pass nearly tangentially to the lateral ventricular walls.

Sagittal tomography gives only a gross view of the profiles of the lateral laryngeal wall, the supraglottic, glottic, and infraglottic regions but it is very difficult to recognize the form of the arytenoids and of the aryepiglottic folds in the roentgenograms. It is useless for the study of the anterior walls of the larynx. While in many cases the deformities are evident and therefore easily recognized in others they are difficult to distinguish and it is impossible to ascertain on what side the lesion is located as the anatomic variation may be such as to mask the pathological deformity. In addition, the deformity of the individual elements may be functional and in this case cannot be differentiated from the anatomic deformity. If there is an anatomic basis it is generally impossible to ascertain its nature whether neoplastic or edematous.

Consequently roentgen examination of laryngeal cancer should not be overestimated but it may add to the clinical examination some elements which otherwise could only be suspected or would escape observation altogether. All other data which it may

furnish (some confirm those obtained by laryngoscopy) serve only as controls and are often debatable when compared with the laryngoscopic findings.

RICHARD KURTZ, M.D.

Angiocardiography: Its Use in the Diagnosis of Patent Ductus Arteriosus. ROA ST. A. FURMAN. *England J. M.* 1947 235 116.

Angiocardiography offers the advantages of visualization of cardiac and great vessel silhouettes. Its chief advantage is that it makes possible the differentiation of mediastinal and vascular pathology from congenital heart lesions.

The diagnosis of congenital heart lesions is especially important in view of the fact that certain of these defects can be corrected by surgery.

Seventy per cent diatrizoate is used as contrast media. Oral or ocular sensitivity tests are made on all patients. To assure proper renal function the phenolsulfonphthalein test should show a 30 per cent reaction. The examination is not done if the patient is hyperthyroid or shows evidence of allergy.

The technique used by the author was a modification of Robb-Steinberg's. A 13 gauge needle with a 30 c.c. syringe were the only implements. The opaque media was injected within a second.

A case is reported in which the accurate diagnosis of a patent ductus arteriosus and traction aneurysm of the descending aorta was not certain until an angiocardiogram was done with subsequent surgical confirmation.

MARTIN H. SACRE, M.D.

The Differentiation of Patent Ductus Arteriosus and Atrial Septal Defect. A. D. VINCOT and DONALD B. ALAN. *Am. J. Surg.* 1947 35 697.

Two of the most common congenital abnormalities of the heart are patent ductus arteriosus and atrial septal defect. Maudie Abbott in studying the postmortem findings in 1,000 cases of congenital cardiac disease, found that patent ductus arteriosus occurred 92 times and atrial septal defect, 73 times. Both defects were present in 16 of these 165 cases.

As is known in patent ductus arteriosus blood from the aorta is shunted to the pulmonary artery. The increased volume of blood results in a dilatation of this vessel and on returning to the heart also causes an enlargement of the left atrium, left ventricle, and first part of the aorta. In atrial septal defect the right atrium receives in addition to the peripheral venous flow a large complement of blood from the left atrium. This leads to great enlargement of the right atrium and ventricle and due to the increased right ventricular systolic output to a considerable enlargement of the entire pulmonary vascular system, while the aorta becomes hypoplastic.

The authors report 6 cases of these abnormalities in which the correct diagnosis was established on the basis of clinical and roentgenological findings. The

TABLE I.—IMPORTANT FACTORS IN THE DIFFERENTIAL DIAGNOSIS OF PATENT DUCTUS ARTERIOSUS AND ATRIAL SEPTAL DEFECT

Patent Ductus Arteriosus	Atrial Septal Defect
1. Normal development after infancy	Subnormal physique
2. No cyanosis	Minimal transient cyanosis
3. Localized pulsation in 2nd left interspace	3. Localized prominence of left anterior chest wall in region of 2nd, 3rd and 4th interspaces
4. Maximal systolic and diastolic thrill	4. Variable thrills
5. Usually typical murmurs	5. Variable murmurs
6. High systolic, low diastolic blood pressure	6. Low systolic blood pressure and narrow pulse pressure
7. Normal electrocardiogram or left axis deviation. Normal sinus rhythm	7. Right axis deviation of electrocardiogram. Large P wave. Various arrhythmias
8. Enlargement of left ventricle and left aorta. Large pulmonary artery. Large aorta	8. Enlargement of right auricle and right ventricle. Great dilatation of pulmonary artery. Hypoplastic aorta
9. Slight circulatory insufficiency	9. Congestive cardiac failure preponderately right-sided
10. Subacute bacterial endocarditis	Acquired valvular heart disease

respective roentgenograms and electrocardiograms are presented for the purpose of illustration of the salient features.

The first case is that of a girl aged 13 in whom a roentgenogram of the chest taken 4 seconds after injection of 50 c.c. of 70 per cent diodrast into the left cubital vein showed left ventricular enlargement, dilatation of the pulmonary artery and a somewhat enlarged aorta, characteristic of patency of the ductus arteriosus. Ligation of the patent ductus caused an immediate fall in the systolic pressure and a rise in the diastolic pressure with return to normal of the peripheral pulse.

The outstanding feature in the second case, that of a female aged 37, was a semicircular line of calcification in the aortic arch superimposed upon the lower part of the aortic knob. At postmortem examination this shadow was seen to outline the aortic opening of a patent ductus arteriosus. Such a finding already described by Weiss is rare.

The third case, that of a female now 43 years old, is notable in that the authors were able to make a comparative study at an interval of 6 years. Roentgenograms of the chest showed the characteristic signs of a patent ductus arteriosus which have progressed slightly during the 6 year period.

The fourth case was mistakenly diagnosed as rheumatic mitral stenosis and closely supervised for a period of 20 years. The patient is a widow aged 46 without symptoms referable to heart disease. A recent roentgenogram of the chest showed all the characteristics of a typical atrial septal defect. The pulmonary artery and its branches as well as the heart were markedly enlarged. The aortic arch was small and there was no chronic passive hyperemia of the lungs.

The fifth case, that of a male 50 years of age likewise was incorrectly diagnosed over a period of years. The presence of a rheumatic heart disease with mitral stenosis and aortic insufficiency was assumed. An examination made recently, however, points to the

fact that the major disorder in this patient was an atrial septal defect although a mitral stenosis (Lutembacher's syndrome) may complicate the picture. As in the fourth case, the outstanding roentgenologic signs were the large transverse diameter of the heart, a marked prominence of the right and main pulmonary arteries and an indefinite aortic arch. In addition there were some positive electrocardiographic signs.

The sixth case, that of a female aged 43 months is perhaps the most illustrative of all. This patient was examined in 1940 when the significance of the roentgenologic signs was not as yet clear. The authors state, in retrospect, it is evident now that the diagnosis was that of atrial septal defect. Over exposed roentgenograms of the chest after diodrast injection showed the right ventricle to represent almost the entire transverse shadow of the heart while the prominent knob above the upper left border of the heart was clearly demonstrated to be a very large pulmonary artery. In a second over-exposed roentgenogram, made 4 seconds later, the aorta appeared smaller than the main pulmonary trunk.

The authors have arranged the main factors which are important from the point of view of differential diagnosis of the two conditions in the table above.

T. LUCUTIA, M.D.

Roentgenologic Study of the Small Intestine Dysfunction Associated with Neurologic Diseases. FRED J. HODGES, R. WAYNE RUNDLES, and JOSEPH HANLICK. *Radiology* 1947 49 659.

The authors have approached the problem of investigating the possible role of the autonomic nerves in causing disturbed motor function of the intestinal tract by carrying out roentgen studies in selected patients with well defined neurologic disease. The patients selected for roentgen study included those with diabetic neuropathy, pernicious anemia, tabes dorsalis, peripheral neuropathy of unknown origin, the Guillain Barre syndrome, peripheral neuropathy

with lead poisoning, autonomic nerve paralysis, and sympathectomy.

Patients in whom the vagus nerves were sectioned in the treatment of intractable peptic ulcer or incidentally during total or subtotal gastric resection were also investigated. The effect of splanchicectomy and lower thoracic ganglionectomy was studied in patients in whom this operation was carried out for the treatment of arterial hypertension.

They present evidence that autonomic nerve disease occurring as an isolated disorder or as one aspect of a more extensive neuropathy may produce grave disturbances in gastrointestinal function.

FRANK L. HERSEY, M.D.

Analysis of Roentgen Ray Diagnosis in Carcinoma of the Cecum and Ascending Colon. CHARLES H. BROWN and JAMES R. COLVERT. *J. Nat. M.* 947: 97, 1936.

The authors analyze the barium enema examinations in 50 cases of carcinoma of the cecum and ascending colon. Correct diagnoses were made in 36 of 50 cases (72%) on the first examination. Ten patients or an additional 20 per cent had to have repeat barium enemas before a diagnosis was made. The reason for the repeat examination in 4 of the cases was that poor preparation had been made for the first examination, and in other cases repeat examination was done because of clinical evidence of malignancy in that area. The barium enemas of 4 or 8 per cent of the proved cases of carcinoma of the cecum or ascending colon were reported as negative for an organic lesion.

With careful technique and preparation, the use of fluoroscopy and films, and doing repeat examinations whenever indicated, the error in roentgen ray diagnosis of an organic lesion can be kept at 10 per cent or less.

FRANK L. HERSEY, M.D.

Aqueous Test in Cholecystography: Its Interpretation and Value. (Sulla "prova idrica" in colecistografia e sulla interpretazione e valore). EMANUELE VITALE. *Rivista med. Milano*, 1947 33: 645.

The observation has been made by the author that in numerous instances in which oral or intravenous administration of the dye for cholecystography did not produce satisfactory results, the ingestion of water or an aqueous suspension of barium sulfate allowed visualization of the gall bladder. As a rule the shadow can be demonstrated within 5 minutes after the ingestion of water or barium and its intensity gradually increases in from 8 to 15 minutes. The mode of the administration of the dye has no effect upon the phenomenon. Apparently the ingested water acts as a stimulus of the duodenohepatic reflex with the result that the flow of bile from the intrahepatic biliary system to the gall bladder is increased. This mobilization of the opaque bile and not a sudden rise of the concentrating power of the mucous membrane of the gall bladder is responsible for the phenomenon under discussion according to the author. Visualization of the hepatic duct after the ingestion of water supports the author's hypothesis. Simultaneously with the rise of the density of the shadow an increased tonus of the previously relatively inactive gall bladder may be observed.

Contrary to Bronner's test which slows up the bile flow from the liver to the gall bladder, the author's test accelerates this flow but prevents the descent of bile from the gall bladder to the duodenum.

The test does not furnish any information as to the emptying power of the gall bladder and therefore should be supplemented by a cholecystokinetic test, such as the ingestion of an egg.

The author claims priority for both the description of the test and the interpretation of its mechanism.

JOSEPH K. ARAT, M.D.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Study of the Morphofunctional Conditions in the Axilla during Phases of the Menstrual Cycle and in Pregnancy (Indagine sul comportamento morfologico e funzionale della ghiandola ghiandolare delle pelle dell'ascella durante le fasi del ciclo mestruale e nella gravidanza) PAOLO CAVAZZANI, *Riv. ginec.* 1947 30 114.

The author studied the morphology and function of the sudoriferous glands in the axilla in 14 women in the third and fourth decades. The effect of menstruation and pregnancy on the glands was investigated.

A moderate degree of activity can be demonstrated in the intermenstrual period. Hypertrophy of a large number of glands during the menstrual period produces an increased number of paraplasmic granules and globules of secretion.

The effect of pregnancy is still more conspicuous. Not only the secreting epithelium but also the muscle cells increase in number and show signs of hypertrophy. Similar changes can be found in other places than the axilla. The increase in the intermenstrual period is detected macroscopically.

These findings corroborate the statement that the sudoriferous glands possess secondary sexual characteristics.

The Redistribution of Body Water and the Fluid Therapy of the Burned Patient OLIVER COPE and FRANCIS D MOORE. *Ann Surg* 1947 125 1010.

The extracellular space was measured in a series of burned patients with other diseases and normal human beings who were dehydrated and given therapy. The measurements included the plasma thiocyanate and radioiodine volumes.

The radioiodine and thiocyanate volumes while almost identical in normal individuals may differ in burned patients. In the first days after injury the radioiodine volume may be larger. In the later days concomitant with wound infection the thiocyanate volume surpasses that of the radioiodine. These discrepancies point to differential cell permeabilities for the two ions.

In the burned patient an expansion of the extracellular space or interstitial space is the important feature of the disordered fluid balance although there is external fluid loss from the wound. The interstitial space is, nonetheless, the chief recipient of the plasma loss. Pressure dressings do not effectively limit the interstitial space expansion. Therapy must be planned to satisfy and not augment this pool of wound edema. Over-treatment will exaggerate the defect and in the extensively burned patient will endanger survival.

609

Measurement of the hourly urine output is the most ready means of checking the adequacy or excess of treatment.

A simple water tolerance test is described which allows a more accurate interpretation of small hourly urine outputs.

All of the fluid which is needed to prevent circulatory failure and dehydration of the body in the first 36 to 48 hours must eventually be excreted by the kidneys or exhaled by the lungs, if it is not lost in the exudate. When resorption of edema is manifest after the forty-eighth hour, fluid therapy must be promptly curtailed to avoid pulmonary edema. In burns of partial thickness the resorption may proceed almost as rapidly as the formation, while in those of full thickness destruction the resorption is generally slower.

The practical application of this knowledge to extensive burns is described. Plans of therapy based upon the anticipated expansion of the interstitial space as well as the surface area burned are outlined for patients with burns of 15 per cent or more of the body surface.

W H NADLER, M D

Progressive Postoperative Cutaneous Gangrene of Amebic Origin (Su di un caso di gangrena cutanea progressiva postoperatoria di origine amebica) ANTONIO BOIANO and FORTICARDO GRANDI. *Boll. Assoc. Soc. parasitol. chir.* 1947 17 594.

Two types of cutaneous lesions of amebic origin may be distinguished:

1. Amebiasis of the skin: a circumscribed lesion located mostly in the perianal region and characterized chiefly by lytic action of the pathogenic factor with a slight inflammatory reaction of the surrounding tissue. It is caused by amebae carried by the blood stream from a distant primary focus.

2. Postoperative gangrene of the skin of amebic origin: In this condition the amebae spread in the tissue with an intensive reaction of the adjoining subcutaneous tissues by continuity from primary focus in the liver, subphrenic spaces, lungs, peritoneal region, and fecal fistulas.

Probably other micro-organisms associated with amebae in such cases produce a synergistic effect. The author describes a progressive postoperative cutaneous gangrene in a 40 year old woman who developed the condition 3 weeks following an operation for liver abscess. No results were obtained from local applications of sulfonamide, potassium permanganate, and Dakin's solution nor from the intramuscular administration of penicillin. The ulcerated area (11x25 cm in diameter) was removed with the electrocautery. The immediate results were good but on the tenth postoperative day signs of recurrence appeared. Energetic treatment with emetin hydrochloride was followed by prompt recovery.

JOSEPH K. NARAY, M D

Lethal Acute Aplastic Anemia following the Use of Streptomycin; Contribution to the Knowledge of the Hematic Reactions Caused by Streptomycin (Anemia aplastica acuta mortale dopo streptomicina, contributo alla conoscenza delle reazioni ematiche da streptomicina). F. COILLI. *Poll. di nice sci. prat.*, 1947, 54, 1055.

This is the first case of lethal acute aplastic anemia after the use of streptomycin to be reported in the literature. It occurred in a woman of 37 who had a tuberculous avelitis was given 81 gm of streptomycin in a period of 54 days and died 10 days after conclusion of this treatment. In addition to the anemia the patient presented a hemorrhagic syndrome due to thrombopenia with obstinate metrorrhagia. Sternal puncture revealed that the functional medullary tissue had completely or nearly completely disappeared the extreme aplasia in showing all three series, the red cells, white cells and platelets. Such a finding together with the clinical picture is sufficient to eliminate the other acute hemopathic syndromes in the differential diagnosis.

The patient had not received any other treatment than the streptomycin had not had any previous tonsillitis or other febrile disease and presented no manifestation of tuberculous activity or of tuberculous localizations she had only her old avelitis. The connections between the treatment and the onset of the blood disease are so intimate that it is impossible to exclude a relation of cause and effect.

Discussing the mechanism by which the streptomycin may have produced the aplastic anemia, Corelli recalls that the English and American authors insist on the particular toxicity of the substance. Undoubtedly some reversible transitory manifestations (urticaria, cutaneous eruptions, eosinophilia) occurring during the treatment may have an allergic pathogenesis but this pathogenesis could hardly be admitted for other manifestations when they have not been accompanied by initial and clear allergic symptoms and when they have appeared after the administration of high or relatively high doses of the substance, the toxicity of which is known.

As to the medullary aplasia, Corelli agrees that some of their postinfective or primary forms due to chemotherapy may have an allergic pathogenesis and may be referable to a myelitis which causes the aplasia. But in the present case there were not enough data to support this hypothesis, and future observations must show whether other contemporary allergic signs lacking in this case will appear.

According to our present state of knowledge concerning streptomycin, it is probable that the severe pancytopenia which occurred after the use of the drug, was of toxic origin. Extreme caution is advised in the use of this substance in cases in which life is not in danger. RICHARD KEMEL, M.D.

VANNI D'ERRICO and PIETRO MAJONE. *Gior. ital. ch.*, 1947, 3, 433.

The object of this study was to determine the hemodynamic and humoral characteristics of tourniquet shock, whether it is possible and in what manner its effects may be prevented or attenuated up to what point and in what manner operative trauma influences the evolution of the shock and the difference between tourniquet and other types of shock. The authors used 8 adult rabbits weighing from 1 to 3 kilograms which were kept under slight sodium pentothal anesthesia during the entire periods of application of the tourniquet to the uppermost part of one or both thighs. The experiments were divided into three groups. In 3 animals shock was produced by applying the tourniquet to one thigh for 5 hours in one and to both thighs for 4 and 7 hours, respectively in the 2 others. In 2 animals atropine was used to study the effect of anticholinergic substances on the prevention or evolution of the shock. In 3 animals the shock was associated with laparotomy and evisceration and the effect of atropine was studied in 2. The results led to the following conclusions.

Tourniquet shock is easily produced if the constriction lasts long enough and if the constriction is bilateral the shock is often lethal. The humoral characteristics of the shock are marked blood concentration (even in reversible shock) leucocytosis or leucopenia depending on the evolution of the shock, hypoproteinemia and hypochloremia.

With atropine it is possible to prevent occurrence of or to influence favorably evolution of shock.

When an animal in moderate shock or in severe but decreasing shock is submitted to laparotomy and evisceration a fall in the blood pressure occurs, which rapidly becomes fatal. This result was also observed when the state of shock was impending or latent and atropine was incapable of stopping the fall in pressure after evisceration. From the practical point of view these experiments confirm the concept that serious risk accompanies any abdominal intervention on a subject in actual or latent shock.

Tourniquet shock presents a blood pressure picture which is practically the same as that observed in shock due to grave nerve trauma. Removal of the tourniquet applied for many hours to both thighs may cause death in little more than one hour as seen after strapping of the two sciatic nerves. Nor is there any substantial difference in the humoral changes, only the blood concentration seems to be more marked in tourniquet shock. Also the fact that this concentration decreases after the operative trauma seems to demonstrate that the loss of plasma which is found in tourniquet shock is greater: this results also from the fibrillation of the tissues of the constricted extremities. However a reduction in the cholinesterase of the serum indicates the use of aretycholine which seems to place the tourniquet shock also in the domain of nervous or rather sympathetic nervous origin. The improvement produced by atropine, a drug paralyzing the parasympathetic, seems to confirm this concept. RICHARD KEMEL, M.D.

Chronic (second) stage of thrombosis in lower extremities, 184. Congenital arteriovenous fistula in internal maxillary artery and pterygoid plexus, 184. Fatality following use of intravenous ether in treatment of peripheral vascular disease, 185. Functional survival of autogenous and homologous transplants of experimental disease, 185. Function of doubly ligated vascular segments as result of thrombolytic, 186. Blood blood in hemorrhagic nervous and humoral factors of post-thrombotic peripheral vasodilatation in dog 307. Stripping of epinephrine veins preliminary report, 391. Action of heparin on experimental venous thrombosis and pulmonary embolism, 391. Traumatic arterial aneurysm, 391. Surgical cure of innominate aneurysm, 392. Sympathectomy as adjunct in operative treatment of aneurysms and arteriovenous fistulas 392. Sympathectomy performed before or at time of operation of aneurysm and arteriovenous fistulas 392. Sympathectomy performed after operation of aneurysm and arteriovenous fistulas 392. Primary acute thrombophlebitis of inferior vena cava, 593. Case of segmental reaction of vena cava, 593. Esophageal varices, 445. Thrombosis of hepatic veins, 493. Budd-Chiari syndrome 454. Carotid body tumor in association with carotid sinus syndrome 501. Vascular effects of tetraethyl ammonium chloride on mixed type of hypertensive carotid sinus syndrome, 515. Neurovascular syndrome of arm associated with hypertrophied subclavius muscle. Report of case including operative treatment, 516. Pulmonary arteriovenous anastomosis 554. Study of vascularization of colon and large in wounds of violence, 597. "Borrowing" hemodynamic phenomenon (hemometakinesis) and therapeutic application in peripheral vascular disturbances, 598. Experimental reproduction of arteriovenous fistula 599.
- Bone.** Associated with spinal cord injuries (paraplegia) 34. Initial lesions in acute osteomyelitis, 78. Treatment of acute osteomyelitis with penicillin. Report on 30 cases, 79. Endophthalmitis with penicillin. Report on 30 cases, 79. Use of absorbable substances to obliterate cavities in and as hemostatic agents in operative procedures on and joints, 80. Use of 83 deposition of radioactive metals in as potential health hazard, 97. Study of eosinophilic granulomas and defects of radius with xanthomas of 179. Repair of from human bite 188. Epileptic of inhalation lead poisoning with characteristic skeletal changes in children involved 195. Roentgen appearance of pri-mary reticulum cell sarcoma of 196. Soft tissue changes in early acute osteomyelitis, 200. Multiple changes and aseptic osteomyelitis, 200. Generalized lipid granulomatosis, 205. Multiple myeloma survey based on 35 cases, 18 of which came to autopsy 256. Benign central cartilaginous tumors of 287. Management of hand injuries, especially treatment of injuries to and joints, 289. Nerve lesions in injuries to and lipomatosis involving 386. Giant-cell tumors of 409. Heterotopic formation of after prostectomy 423. Injuries of and bone-marrow after intravenous infusion, 425. Neuroendocrine syndrome in 425. Hansen's disease, 425. Case of disseminated tuberculosis osteitis polyosteoarthritis in Recklinghausen's syndrome 485. Osteoid osteoma—A review of literature and report of 30 cases, 486. Eosinophilic granuloma of 487. Eichenboeck's disease (softening of bone) following slow healing of wrist in work accidents, 488. Large pseudocyst of tibia, result of chronic staphylococcus osteomyelitis, 489. Treatment of chronic osteomyelitis by use of spongy grafting of 489. Dislocation of semilunar with special consideration of atypical case 490. Osteochondroma or circumscribed fibrous cystic osteochondroma or circumscribed 588. Osteoporosis, 593. Grafts of end result of healing time, 595.
- Bones.** Method for treatment of fractures of expanded ends of long, 493. Intramedullary metallic fixation in treatment of fractures of long results in 38 cases, 493. Ollier's disease and relation to other forms of chondrodysplasia, 582.
- Brachial plexus.** Tendonous reconstruction of hand following irreparable injury to peripheral nerves and 180. Paradoxical contractions of muscles in course of obstetrical paralyzes of synergistic disturbances 49.
- Bracket operation for ununited fracture of neck of femur 592.**
- Brain.** Diagnostic significance of ocular pals in craniocerebral trauma, 33. Partial excision of motor cortex in cases, 33. Meningiomas of cerebellum, results in 41. Study of 160 cases including mortality and end results, 152. Penicillin in prevention of infection during operations on, and spinal cord, 154. Technique of direct (percutaneous) cerebral angiography of 192. Irradiation of experimental cerebral tumors experimental).

- production of brain tumors in mice 199 roentgenography with small amounts of air 350 multiple meningiomas 353 neuromas of cerebellopontine recess clinical study of 60 cases, including overall mortality and end results correction 350 symmetrical calcification of basal ganglia of, roentgenologic significance in diagnosis of parathyroid insufficiency 41 cerebral arteriography 439 treatment of focal epilepsy by cortical excision, 439, some views of glioblastomas according to Scherer 440 cerebral angiography 509 blunt injuries of skull and, 546
- Breast.** Anatomic and clinical types of tuberculous of tuberculous galactosporitis, 56 peroperative roentgen treatment in cancer of 94 treatment of cancer of the estrogenic hormones, 37 use of testosterone propionate in treatment of ad cancer metastases of treatment of ovarian metastases, 37 hormonal alteration of ad cancer of 39 cystic disease of human and experimental, 333 radical mastectomy prognosis after survival for 5 years, 333 roentgen therapy in chronic mastitis, 40 telereöntgenotherapy of cancer of especially in inoperable cases 40 cancer of male secondary to estrogenic administration, 484 amputation versus transposition of gland and nipple in mamma plecty 549 cystic mastitis and cancer of, 551
- Bronchi.** Study of variations of segments of in left upper lobe 239
- Bronchiectasia.** Pathogenesis of 354 anesthesia in surgical treatment of 60
- Bronchus.** Traumatic rupture of 24 carcinomas of with special reference to treatment by radiotherapy 52
- Brucellosis.** Oropharyngitis. Importance of 453
- Burns.** Further experience with minic roentgen graft capsule of 32 studies of thermal injury exploration of causality-producing attributes of configurations local and systemic effects of general cutaneous exposure to extensive circumambient (air) and circumambient heat of varying duration and intensity 3 predictability and significance of thermally induced rate processes leading to irreversible epidermal injury 103 specific treatment of oedema due to leucitis (8-chloro-lythichloroaniline) 24 ascorbic acid, thiamine riboflavin, and nicotinic acid in relation to acute, in man, 504 role of leucostatin in production of anhydrosis of shock due to, 50 redistribution of body water and fluid therapy of patient with, 600
- Buttock.** Amelioration of left, 601
- CALCANEUS.** Treatment of fractures of os calcis by open reduction and internal fixation 593 coracoclavicular and treatment of fractures of open reduction with use of cancellous grafts, 593
- Calcification.** Roentgen demonstration of in interventricular septum in cases of heart block, 403 data on occurrence of in eye lenses, 556
- Calculus.** Roentgenologic diagnosis of appendical, 94 hepatic, 265 method of dissolution of common duct, remaining after operation, 455 multiple of urinary bladder 580
- Calculus.** Chemical investigation of enterolith in Greville's case and report of further case of primary of small intestine 5
- Calliper.** Walking, 39
- Cancer.** Of parathyroid glands, with preliminary report of 3 cases collective review 1 Eschlander Abbe operation in treating secondary hand deformities and defects of upper lip revealing from 8 of tonsil, 30 attempt to identify likely precursors of gastric, 46 cytology of gastric fluid in diagnosis of stomach, 46 radical of surgical treatment of gastric, 47 of colon and distal of operative technique 56 surgical treatment of of rectum and sigmoid 56 preoperative roentgen treatment of breast 94 of cervix, 94 retention of radioactive iodine in thyroid histopathologic and radioautographic studies, 91 of skin influence of dosage on success of treatment, 95 treatment of 95 radioactive phosphorus as external therapeutic agent in sarcoma, hemangioma, and basal cell, 96 of thyroid, 130 nature and characteristic features of laterocervical bronchogenic, 131 treatment of of breast with estrogenic hormones, 37 use of testosterone propionate in treatment of ad cancer, of breast treatment of ovarian metastases, 337 bronchogenic (clinical-pathologic study of 36 autopsied cases seen at Brooklyn Instit 1 for bet cen 1937 and 1945 inclusive 138 primary of lung with invasion of ribs, 130 gastric, 138 statistical study of 1,405 cases of of stomach 138 irradiation of gastric, 133 management of of colon, 136 management of in several parts of colon, 136 external irradiating surgery of of uterus justified in light of modern knowledge 161 primary of ureter 177 of bladder 173 primary of male urethra 174 planigraphy in diagnosis of bronchogenic 193 treatment of recurrences and evaluation of criteria for selection of treatment of of larynx, 200 intrinsic of larynx: review of series of cases, 213 hormonal alteration of ad cancer, of breast, 30 primary of lung 223 induction of bronchogenic, in mice, 223 bronchogenic, 225 of esophagus, 227 of stomach, 231 of colon 261 cervical disordered growth response to inflammation in presence of estrogen excess and nutritional deficiency 264 of uterus, 264 radium therapy of, of uterine cervix and of fundus, 265 primary of male urethra, 266 paths of biosthery of 312 of middle ear and mastoid process, 330 of thyroid 348 of pituitary gland with metastases to liver in case of Cushing's syndrome 350 of esophagus and cardiac end of stomach, 356 consideration of pathologic factors influencing 5 year survival in radical resection of large bowel and rectum for 362 of rectum, 504 treatment of uterus 370 primary of apex brief review of literature and reports of 4 cases, 372 treatment of of vul 373 of bladder 383 telereöntgenotherapy of of breast especially in inoperable cases, 402 protein-chemical aspects of, 411 of the rostral gland anatomical types, evolution and results of treatment in 35 cases, 436 treatment of lymph node metastases from intracranial, with special regard to indications for total neck dissection, 437 clinical and radiologic features of lymphatic metastases in of thymic esophagus, 443 of stomach, from radiologist's point of view 444 gastroscopy in diagnosis of gastric 450, of stomach some pathologic considerations, 450 surgical aspect of of stomach, 451 of ampulla of Vater 453 of large intestine 453 of islets of Langerhans: review of literature, 457 treatment of bladder 481 of male breast secondary to estrogenic administration, 484, of bronchus with special reference to treatment by radiotherapy 512 further observation with intravaginal roentgen therapy of, of female pelvis, 512 incidence of gastric; collective review 52 clinical significance of examination of mesenteric lymph nodes in, 543 cystic mastitis and, of breast, 55 of cases of lung evaluation and importance for physician 55 acute perforation of gastric, 557 irradiation of gastric, 557 statistical approach to gastric, 558, rectosigmoid, and of distal sigmoid resection and primary anastomosis, 56 preoperative of cervix ter 7 cases in which it is detected by examination of routine endocervical smears, 568 invasion of cervical, into parametrium and vagina, 568 results in management of cervical, in

- Traction, Correction of retractions of extremities by slow bloodless procedure, 200 intertrochanteric fractures of femur; treatment in, and by internal fixation, 495
- Transfusion, Deaerated calf plasma for 295
- Trauma, Tolerance dose and prevention of injuries caused by ionizing radiations, 20, effects of total surface beta irradiation, 202 on problem of and aseptic osteocrosis, 86 adrenal cholesterol and ascorbic acid contents after injury 414, palliative operations in patients of upper limb, 497; metabolic disturbances after injury 514 blunt injuries of skull and brain, 516 cases of rupture of normal spleen, 566 joint mobility

- ly operations on hip, knee and shoulder for emphysema following 585 experimental research on shock by operative shock from tourniquet, 610
- Tidder** Visual effects of 430
- Tryptophan**, Ocular involvement in rats on diets deficient in amino acids, 335
- Tuberculosis**, Ocular retinitis of Jensen 33 anatomic and clinical types of mammary palatophoritis due to 36 tuberculosis and pneumonitis in pulmonary 38 lung resection for pulmonary 38 case of multiple hyperplasia of colon 155 and pregnancy 165 pregnancy complication 271 2 cases of of thyroid gland 436 significance of hematuria in renal, 476 of terminal portion of ureter, 479 high resection of vas deferens in genital, 484 bridge arthrodesis for of pulvis 493 decontamination in chronic empyema due to 552 contribution to knowledge of surgical forms of gastric 557, endometritis due to, 567 evolution of pulmonary, after delivery 574 control of urinary, 581 retroperitoneal 1 vertebrae as early sign of spondylitis of lumbar spine due to, 553
- Tumors**, Carcinoma of parathyroid glands with preliminary report of 3 cases collective review 1 mixed of urinary gland type 20 pernicious anemia and, of stomach, 45 benign of small intestine 52 Meigs's syndrome case report and review of recently published cases, 61 management of ovarian complicating pregnancy 67 of kidney 2 biological assay of kidney by heterologous ocular transplantation 72 experimental investigations of leucemias and of reticuloendothelial system, 87 myosarcoma gravid and, 1 thyroid, clinical and anatomopathologic study 98 involving petrous pyramid of temporal bone 125 alar nasal papilliferous keratoid, 131; epula, 138 anomaly of aorta stimulating mediastinal 141 classification of ovaries based upon histogenesis, 161 clinical and pathologic-anatomical study of of kidney in children based on series of 18 cases, 172 irradiation of experimental cerebral experimental production of brain, in mice 199 neurogenic, of nose and throat 231 papillary cystadenolymphoma 232 simultaneous chromatin of carotid body and glomus jugularis, 232 malignant lymphoma of lung and pulmonary coarctation of aorta, 241 treatment of, serious, of bladder 278 on malignant, of testicle 284 glandular metaplastic malignancy 285 multiple myeloma survey based on 33 cases, 18 of which came to autopsy 286, benign central cartilaginous, of bone 287 preparation of radioautographs of thyroid, for study of high magnification 307 etiology of endometriosis collective review 313 clinical significance of malignant, of thyroid gland, 318 benign intestinal, of vascular origin 361; takum powder granuloma frequent and serious postoperative complication 361 sarcoma botryoides vaginae complete excision of in infant by combined abdominal and perineal approach, 372 adrenal, and pseudodermoid phorbol hormone study of cases, 381 malignant of small intestine, 406 giant-cell of bone, 409 experience in surgical treatment of multiple visceral, 413 intrascapular, of maxilla, 434 unusual of sternum, 443 of mesentery 448 benign of stomach national statistics, 449, carcinoid, of stomach, 449 anatomical contribution to knowledge of granulosa cell, 460 pheochromocytoma, 473 papillomatous disease of renal pelvis, 477 Wilms's, 478, 478 retroperitoneal, of Gerota's pararenal adipose space, 479 disembranchment of bladder chondrosarcoma, 481 malignant epithelial, of testicles, 483 carotid body, in association with carotid sinus syndrome 501 differentiation of mediastinal, and aneurysm by angiocardiology 510 sarcomatous clinical and roentgenologic study of 58
- proved cases 517 neoplastic disease of thyroid gland, 544 mediastinal enterocystoma 554 osteofibroma or circumscribed fibrous cystic osteodystrophy 582 giant cell, of lumbar spine 583
- Tympanic membrane** Rupture of of blast origin 25 closure of perforations of 26
- UCLER**, Case of recurrent aphthous urethritis with associated ulcer vulvae acutum (Lipshuetz) 23 nutritional state of patients with peptic, as measured by vitamin levels in blood and urine, 44 importance of malignant degeneration as complication of chronic colitis with, 55 operative treatment of decubitus, 99 effect of enterogastrostomy on Mann Williamson, in dogs 147 effect of vagotomy on Mann Williamson, in dogs, 148 resection of vagus nerves for, interim evaluation operative technique and hospital management, 148 section of vagus nerves to stomach in treatment of benign gastric, 148 clinical evaluation of complications inserted after transabdominal vagotomy, 149 partial gastrectomy for atrophic 150, effect of radiation therapy on nocturnal gastric secretion in patients with duodenal correction, 160 experimental production of in low gastric pouches in dogs, 208 gastric neurotomy for gastric and duodenal, 250 subtotal gastrectomy for gastric, 251 peptic diagnostic and therapeutic problem 252 gastric neurotomy anatomic and physiologic studies with favorable and unfavorable results in treatment of peptic, 254 management of patients with massive hemorrhage from peptic 254 vagus resection for interim evaluation 256 some physiologic aspects of surgical treatment of duodenal 256 tropical, 310 role of hostility in pathogenesis of peptic, 358 place of surgery in treatment of peptic Hamilton Russell memorial lecture 359 symposium on vagotomy for peptic experimental observations, 359 symposium on vagotomy for peptic early surgical results in 43 cases, 360 symposium on vagotomy for peptic medical aspects of vagotomy for peptic including observations on clinical value of insulin test and postoperative criteria for completeness of bilateral gastric vagus section 360 section of vagus nerves to stomach in treatment of peptic, 448 treatment of perforated corneal by autoplasmic scleral transplantation 536 psychosomatic considerations in peptic 350 15 years' experience with free feeding of patients with bleeding peptic fatal cases, 560 study of results, both favorable and unfavorable, of section of vagus nerves in treatment of peptic, 560
- Umbilicus**, Massive congenital hernia of (amniotic hernia) 447 creeping infection of 573
- Uremia**, Nitrogen and fluid balance in treatment of acute, by peritoneal lavage, analysis of peritoneal washings for protein, nonprotein nitrogen and phosphorus, 368
- Ureter** Surgical care of urinary incontinence in women 63 primary carcinoma of 272 transplantation of and cystectomy 277 diverticulum of 383 tuberculosis of terminal portion of 470 cystectomy and transplantation of 479 anatomical of intestines and, 577
- Urethra**, Primary carcinoma of male 274 artificial sphincter, 278 primary carcinoma of male 280 diverticulum of female, 463 urethroceles, 463 diverticulum of 482
- Urinary tract**, Surgical care of incontinence of in women 63 treatment of paraplegic, 73 functional and morphologic reactions of, during course and wane of nephritic colic, 77 surgical treatment of stress incontinence in female report of 47 cases, 463 urethroceles, 463 renal salvage 476 intraperitoneal rupture of bladder 481 excretory urography by intramuscular route in adults, 483 development of artificial kidney experi

- mental and clinical experiences, 520. Interoesophageal anastomosis, 577. Control of tuberculosis of 58.
- Urography. Excretory. Intramuscular route in adults, 453.
- Urology. In European theater. World War II, 75. In naval medical corps. World War II, 75.
- Uterus. Accommodation of products of conception to physiologic considerations, 69. Cancer of cervix, 94. Is extensive mutilating surgery of cancer of, justified in light of modern knowledge, 6. Discussion of preference for total abdominal hysterectomy instead of subtotal hysterectomy. 6. Radium therapy of hemangio-endothelioma of cervix of, 304. In stigilosis into mucosa of pathologic and clinical classification of metropathia hemorrhagica, 164. Cervical cancer. Disordered growth response to inflammation in presence of estrogen excess and nutritional deficiency. 364. Cancer of. 364. Radium therapy of cancer of cervix of and of fundus, 365. Rare ectopic pregnancy in left cornu of 365. Treatment of cancer of. 370. Personal method for surgical cure of retroflexion of. 458. Radical and conservative treatment of ruptures of. 458. New experimental contribution to study of pathogenesis of fibromyoma of. 458. Data on treatment of fibromyoma of observed in. 945 and 946 at Obstetric and Gynecologic Clinic of Strasbourg. 459. Limits of differential histopathologic diagnosis between adenocarcinoma of cervix and adenocarcinoma of body of. 460. Postabortal phlegmonous gangrene of cervix of. 460. Obstetrical accidents of. Electrocoagulation of cervix, 474. Röntgen therapy in fibromyoma of without ovarian sterilization. 5. Endometritis tuberculosa, 567. Fibroids of, 567. Preinvasive carcinoma of cervix of, 7. Cases in which it was detected by means of routine endocervical smears, 568. Precursors of corpus carcinomae uterinae and adenocarcinoma hyperplasia, 569.
- Urethra. Case of recurrent epithelioma with oleus vulvae acutum (Lipichuetis). 13. Bilateral, from bowen's disease, 130.

VAGINA. Microbial pictures in ureans from new classification of bloodstains of, into 6 basic types, 163. Relationship of, to adjacent organs in reconstructive surgery. Histologic study. 365. Enterococci or posterior hernia of, 37. Occurrence of enterococci in, of, 379. Primary carcinoma of. Brief review of literature and reports of 4 cases, 378. Carcinoma botryoides vaginae; complete excision of tumor in infant by combined abdominal and perineal approach, 378. Correlation between smear from, and tissue diagnosis in 1,045 gynecologic cases in which operation was done, 375. Roentgenological study and surgical treatment of congenital transverse occlusion of, 461. Invasion of cervical carcinoma into parametrium and, 568.

Vagotomy. Effect of on Mann-Williamson ulcers in dogs, 128. Clinical evaluation of complications observed after transthoracic, 140. Effect of on human gastric function, 50. Symposium on, for peptic ulcer: experimental observations, 359. Symposium on, for peptic ulcer: early surgical results in 43 cases, 360. Symposium on, for peptic ulcer: medical aspects. Clinical value of insulin test and postoperative criteria for completeness of bilateral gastric vagus section, 360.

Vagus nerves. Anatomic variations of significance in resection of, 40. Resection of for ulcer. Interim evaluation. Operative technique and hospital management, 48. Section of to stomach in treatment of benign gastric ulcer. 48. Vagus resection for ulcer. Interim evaluation, 56.

Vulvae. Ocular changes in rats on diets deficient in amino acids, corneal dystrophy due to deficiency of 333.

Variates. Sclerotherapy of esophageal, 346.

Vas deferens. High resection of in genital tuberculosis, 484.

Veins. Phlebography for study of obstruction of of superior vena caval system, 84. Surgical pursuit and removal of metallic foreign body from systemic circulation of, 84. Absorbable fibrin tubes for anastomoses of, 85. Study of results of surgical treatment of varicose, 183. Effects on venous endothelium of alterations in blood flow through vessels in walls of and possible relation to thrombosis, 183. Gastroesophageal resection and total gastrectomy in treatment of bleeding varicose, 184. Hant's syndrome, 240. Postthrombotic sequelae of lower extremities: treatment by interruption of superficial femoral and stripping of saphenous, (preliminary report) 89. Systems of in pericardium, 573.

Vena cava. Necessity of immediate intervention in phlebitis of inferior case of segmental resection of 303. Primary septic thrombophlebitis of inferior 303. Vascular responses in man to ligation of inferior 307; roentgen visualization of inferior 5.

Venography. Abdominal, 51.

Vernium verile. Treatment of eclampsia and pre-eclampsia with, and magnesium sulfate, 377.

Vertigo. Dentone, tinnitus, neuralgia, and 25. Physiology of vestibular mechanism in relation to, 346. Pathology of arising from peripheral vestibular apparatus, 347.

Vinyl chloride. Anesthesia, narcosis with, 91.

Virilism. Contribution to diagnosis and treatment of, 104. Viscero-rayograms in cystourethrography. 173.

Vitamins. Nutritional state of patients with peptic ulcer as measured by levels of in blood and urine. 44.

Vitrore. Substitution of spinal fluid for 125. Transplantation of, 430.

Volkman's contracture. Fundamental concepts and treatment of completely developed, 583.

Valve. Leucoplakia of 373. Treatment of carcinoma of, 373.

WAR, Urology in European theater. Second World, 75. Urology in naval medical corps, Second World, 75. Wounds of genito-urinary tract, 76. Injuries of peripheral nerves in, 134. Ocular injuries in soldiers, 125. Partial denture prosthesis for injuries of, 232. Management of colonostomies performed for injuries of 260. Survey of pathologic specimens from oral regions seen at Army Institute of Pathology during World War II, 433. Intraocular foreign bodies in soldiers, 315. Injuries to hip joints, dislocations of World War II, 591.

Warts. Radioactive phosphorus as external therapeutic agent in basal cell carcinoma. hemangioma, and, 96.

Water. Redistribution of body and fluid therapy of burned patient, 609.

Wilm's tumor. 478, 478.

Wounds. War of genito-urinary tract, 76. Effect of powdered whole blood cells and plasma on healing of. 93; bullet, 41. Plastic operative procedure for repair of large circular and elliptical body surface defects, 205. Experiences with thoracic and thoracoabdominal, in evacuation hospital, 240; (frothing, 299). Injuries of chest, 355; of heart, 9 cases, 444. Management of injuries to large blood vessels in, of violence, 597.

Wrist. Metacarpal reconstruction, 358. Synovitis of, 387. Kienbock's disease (softening of scaphoid bone) following slow healing of, in work accidents, 484. Medical considerations following injuries of, 483. Dislocation of scaphoid bone with special consideration of typical case, 496. Fundamental concepts and treatment of Volkman's completely developed contracture, 583. Fracture of carpal scaphoid, 590.

XANTHOMA. Contribution to study of eosinophilic granulomas and their relation to bony 179.
